CONTRIBUTORS

ALFRED W ADSON B Sc., M A., M D., M S in Surgery F A C S
Senior Neurosurgeon The Mayo Clinic Professor of Neurosurgery The Mayo Foundation for Medical Education and Research Graduate School University of Minnesota, Minneapolis, Minn

FULLER ALBRIGHT M D
Associate Professor in Medicine, Harvard Medical School Boston Physician Massachusetts General Hospital, Boston Mass

HARRY L ALEXANDER M D
Professor of Clinical Medicine, Washington University Medical School Associate Physician Barnes Hospital St Louis Mo

WALTER C ALVAREZ M D
A Senior Consultant in Division of Medicine The Mayo Clinic and Professor of Medicine The Mayo Foundation for Medical Education and Research Graduate School University of Minnesota, Minneapolis, Minn

J BURNS AMBERSON Jr., M D
Professor of Medicine College of Physicians and Surgeons Columbia University Visiting Physician in Charge, Tuberculous Service Bellevue Hospital New York

HAROLD L. AMOSS B S M S M D., Dr P H., Sc D (Hon)
Consulting Physician Greenwich Hospital Conn White Plains Hospital White Plains N Y United Hospital Port Chester N Y., and Grasslands Hospital Valhalla N Y

DONALD G ANDERSON M D
Instructor in Medicine The Boston University School of Medicine Research Fellow in Medicine The Evans Memorial Massachusetts Memorial Hospital

ROBERT GARDINER ARMOUR, B A M B F R C P (C)
Associate in Medicine University of Toronto Assistant Attending Physician Toronto General Hospital, Toronto Ont., Canada.

DANA WINSLOW ATCHLEY M D
Professor of Clinical Medicine College of Physicians and Surgeons Columbia University Associate Visiting Physician Presbyterian Hospital New York

JOSEPH C AUB A B., M D
Associate Professor of Medicine Harvard Medical School Physician in-Chief Collis P Huntington Memorial Hospital Boston Mass Physician Massachusetts General Hospital Boston Mass

JAMES BOURNE AYER M D
Professor of Neurology Harvard Medical School Boston Mass

GEORGE BAEHR, M D
Clinical Professor of Medicine Columbia University Physician to the Mount Sinai Hospital New York City Consulting Physician St Joseph's Hospital and Rockaway Beach Hospital New York and Monmouth Memorial Hospital, Long Branch N J

DONALD CHURCH BALFOUR D Sc., M D F R.C S (England) F A C S., LL D F R C S (Aust)
Professor of Surgery and Director The Mayo Foundation University of Minnesota Head of a Section in Surgery The Mayo Clinic, Rochester Minn

ALVAN L BARACH M D
Associate Professor of Clinical Medicine Columbia College of Physicians and Surgeons New York

DAVID PRESWICK BARR, A B M D., LL D
Professor of Medicine Cornell University Medical College Physician in-Chief New York Hospital New York

WALTER BAUER, M D
Associate Professor and Tutor in Medicine Harvard Medical School Boston Massachusetts Physician Massachusetts General Hospital Boston Mass

STANHOPE BAYNE-JONES M D
Professor of Bacteriology Yale University School of Medicine New Haven Conn

FRANCIS GILMAN BLAKE A B., M A., M D., Sc. D
Sterling Professor of Medicine and Dean of the Medical School Yale University Physician in Chief to the New Haven Hospital New Haven Conn

SAMUEL BRADBURY M D
Medical Director Out Patient Department, Pennsylvania Hospital Visiting Physician Germantown Hospital Philadelphia, Pa

WILLIAM L BRADFORD B A M D
Associate Professor of Pediatrics University of Rochester School of Medicine and Dentistry Associate Pediatrician Strong Memorial and Rochester Municipal Hospitals Rochester N Y

W B CASTLE M D S M., M D (Hon)
Professor of Medicine Harvard University Associate Director Thorndike Memorial Laboratory Director Second and Fourth Medical Services (Harvard) Boston City Hospital Boston Mass

RUSSELL L CECIL A B M D Sc D F A C P
Professor of Clinical Medicine Cornell University Medical College Attending Physician New York Hospital Visiting Physician Bellevue Hospital New York

CLARENCE E DE LA CHAPELLE M D F A C P
Professor of Clinical Medicine New York University College of Medicine Lecturer in Medicine New York University College of Dentistry Visiting Physician Bellevue Hospital Associate Physician and Chief of Cardiac Clinic, Lenox Hill Hospital Physician to the Bellevue Schools of Nursing New York University New York

HENRY THORNDIKE CHICKERING A B M D
Assistant Professor of Clinical Medicine Columbia University New York

L T COGGESHALL M D
Professor of Epidemiology School of Public Health University of Michigan Ann Arbor Michigan

ROBERT ANDERSON COOKE A B A M M D, Sc D (Hon)
Attending Physician Roosevelt Hospital Director Department of Allergy Roosevelt Hospital New York

BURRILL B CROHN M D
Associate in Medicine (Gastro-enterology) Mt Sinai Hospital Associate in Medicine (Post graduate) Columbia University New York

BRONSON CROTHERS M D
Assistant Professor of Pediatrics Harvard Medical School Visiting Physician The Children s and The Infants Hospitals Boston Mass

LOYAL DAVIS M S M D, Ph D
Professor of Surgery and Chairman of Division of Surgery Northwestern University Medical School Attending Surgeon Passavant Memorial Hospital Chicago Ill

THOMAS KIRBY DAVIS A B M D
Clinical Professor of Neurology New York University Attending Neuropsychiatrist, Lenox Hill Hospital Attending Neurologist, Hospital for Ruptured and Crippled Consulting Neurologist New York Eye and Ear Infirmary New York

M HENRY DAWSON M D
Associate Professor of Clinical Medicine Columbia University Associate Attending Physician Presbyterian Hospital and Vanderbilt Clinic New York

MICHAEL E DeBAKEY M D
Assistant Professor of Surgery School of Medicine Tulane University Associate in Surgery Ochsner Clinic Visiting Surgeon Charity Hospital Member of Staff Touro Infirmary New Orleans La

ARTHUR CHRISTIAN DeGRAFF B S, M D
Professor of Therapeutics New York University College of Medicine Chief New York University Cardiac Clinic Lecturer in Medicine New York University College of Dentistry Visiting Physician Bellevue Hospital Consulting Cardiologist New York Infirmary for Women and Children Meadowbrook and Nassau Hospitals St Agnes Hospital (White Plains N Y) and Hackensack Hospital, Hackensack N J

DEREK DENNY BROWN M B, Ph D F R C P
Professor of Neurology Harvard University Director Neurological Unit Boston City Hospital Boston Mass

HERBERT K DETWEILER M B M D (Tor) F R C P (C)
Assistant Professor of Medicine and Clinical Medicine University of Toronto Physician in Chief Toronto Western Hospital Toronto Canada

*RAYMOND L DITMARS Litt D
Late Curator of Mammals and Reptiles New York Zoological Park New York

H LAURENCE DOWD A B, M D
Associate Attending Pediatrician City Hospital New York City Chief of City Pediatric Clinic Visiting Physician Southampton Hospital New York

EUGENE F DuBOIS A B M D
Professor of Physiology Cornell University Medical College Attending Physician New York Hospital Medical Director Russell Sage Institute of Pathology New York

CARY EGGLESTON M D
Associate Professor of Clinical Medicine Cornell University Medical College Visiting Physician Second (Cornell) Medical Division Bellevue Hospital Attending Physician New York Hospital Consultant New York Infirmary for Women and Children Consultant Cardiologist Hospital for Ruptured and Crippled Willard Parker Hospital New York

ERNEST CARROLL FAUST Ph D
Professor of Parasitology Department of Tropical Medicine Tulane University of Louisiana New Orleans Member Hutchinson Medical Clinic Consultant to the Secretary of War on Tropical Medicine and on Epidemic Diseases Consultant U S Public Health Service New Orleans La

MAXWELL FINLAND M D
Harvard University and Medical School Chief Fourth Medical Service Boston City Hospital Associate Physician Thorndike Memorial Laboratory Boston City Hospital Assistant Professor of Medicine Harvard Medical School Boston Mass

WARFIELD M FIROR, M D
Visiting Surgeon Johns Hopkins Hospital Baltimore Md

Deceased

CONTRIBUTORS

LeROY D FOTHERGILL, M D
Assistant Professor of Bacteriology and Immunology Harvard Medical School Boston Mass

EMANUEL DAVID FRIEDMAN B S., M D
Professor of Neurology and Chairman of Department, New York University College of Medicine Visiting Physician Neurological Service Bellevue Hospital Attending Physician Neuropsychiatric Division Beth Israel Hospital New York City Consulting Neurologist, Jersey City Hospital Jersey City N J

CHANNING FROTHINGHAM A B., M D
Chief of Medical Service Faulkner Hospital Boston Mass

ERNEST W GOODPASTURE, M D
Professor of Pathology Vanderbilt University Medical School Nashville, Tenn

L WHITTINGTON GORHAM B A., M D
Professor of Medicine, Albany Medical College Medical Department, Union University Physician in Chief Albany Hospital Albany N Y

SAMUEL B HADDEN M D
Assistant Professor of Neurology University of Pennsylvania School of Medicine Visiting Neurologist, Philadelphia General Hospital Philadelphia, Pa. Neurologist, Presbyterian Hospital Philadelphia, Pa., Consulting Neurologist, Bryn Mawr Hospital Bryn Mawr Pa

FREDERIC M HANES A B., A M., M D
Florence McAlister Professor of Medicine Duke University School of Medicine, Durham N C

FRANKLIN M HANGER, B S., M D
Associate Professor of Medicine Columbia University Associate Attending Physician Presbyterian Hospital New York

D L HARRIS M D
Director Pasteur Clinic, Health Division St Louis, Mo

J M HAYMAN Jr., A B M D
Professor of Clinical Medicine and Therapeutics, Western Reserve University School of Medicine Cleveland, Associate Physician Lakeside Hospital Cleveland O

CLYDE ALEXANDER HEATLY A B M D F A C S
Associate Professor of Surgery in Charge of Otorhinolaryngology and Bronchoscopy University of Rochester School of Medicine and Dentistry Rochester N Y., Chief of Otorhinolaryngology and Bronchoscopy Strong Memorial and Municipal Hospitals Rochester N Y., Consultant Rochester General Genesee and Highland Hospitals Rochester N Y., and Mount Morris Tuberculosis Hospital, Mount Morris N Y

HENRY F HELMHOLZ B S M D
Head of Section on Pediatrics The Mayo Clinic Professor of Pediatrics The Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota, Minneapolis Minn

PHILIP S HENCH B A., M D., M S in Medicine F A C P., Sc. D (Hon)
Head of Section in Division of Medicine The Mayo Clinic Associate Professor of Medicine The Mayo Foundation Rochester Minn

WILLIAM WORTHINGTON HERRICK, A B M D
Professor of Clinical Medicine College of Physicians and Surgeons Columbia University Attending Physician, Presbyterian and Sloane Hospitals New York

GEORGE J HEUER, M D
Professor of Surgery Cornell University Medical College and Surgeon in Chief to the New York Hospital New York

HUBERT S HOWE A B A M., M D
Clinical Professor of Neurology Columbia University New York

JAMES H HUDDLESON A B A M., M D
Chief Neuropsychiatric Research Unit, Veterans Facility Northport, N Y

GEORGE HALL HYSLOP A B A M., M D
Assistant Clinical Professor of Neurology College of Physicians and Surgeons Columbia University Attending Neurologist, New York Neurological Institute Neurologist to Memorial Hospital New York.

ERNEST E IRONS M D Ph D
Clinical Professor of Medicine University of Illinois Medical School Attending Physician Presbyterian Hospital, Chicago Ill

HENRY JACKSON Jr M D
Assistant Professor of Medicine Harvard University Assistant Visiting Physician Boston City Hospital Associate Physician Thorndike Memorial Laboratory Physician Pondville Hospital Wrentham Mass

CHARLES ALDERSON JANEWAY M D
Assistant Professor of Pediatrics Harvard Medical School Visiting Physician Children's Hospital Boston Associate in Medicine Peter Bent Brigham Hospital Boston Consultant in Bacteriology Boston Lying In Hospital Boston Mass

CHESTER M JONES A B M D
Clinical Professor of Medicine Harvard University Physician Massachusetts General Hospital Boston Mass

CHESTER SCOTT KEEFER, M D., F A C P
Director Evans Memorial Massachusetts Memorial Hospitals Wade Professor of Medicine Boston University School of Medicine Boston Mass

FOSTER KENNEDY M D, F R S (Edin)
Professor of Clinical Neurology Cornell University Medical College Attending Physician New York Hospital Visiting Physician in Charge of Neurological Service Bellevue Hospital New York

RALPH KINSELLA A M, M D
Professor of Internal Medicine and Director of Department, St Louis University School of Medicine St Louis Mo

LAWRENCE KOLB M D
Assistant Surgeon General in Charge of Division of Mental Hygiene United States Public Health Service, Washington D C

WALTER M KRAUS, A B A M, M D
Formerly Associate in Neurology Cornell University Assistant Neurologist, Bellevue Hospital Associate Neurologist Neurological Institute Neuropathologist and Attending Physician Montefiore Hospital, New York

EDWARD B KRUMBHAAR, A B, M D Ph D
Professor of Pathology University of Pennsylvania Pathologist, University Hospital Consulting Pathologist, Philadelphia General Hospital Philadelphia and Bryn Mawr Hospital Bryn Mawr Pa

EUGENE M LANDIS M D Ph D
George Higginson Professor of Physiology Harvard Medical School Boston Mass formerly Professor of Internal Medicine University of Virginia, Charlottesville Va.

WILLIAM GORDON LENNOX M D, Sc D
Assistant Professor of Neurology Harvard Medical School Visiting Neurologist Boston City Hospital Boston Mass

ROBERT L LEVY A B, M D
Professor of Clinical Medicine College of Physicians and Surgeons Columbia University Associate Attending Physician Presbyterian Hospital Consulting Cardiologist French Hospital New York Infirmary for Women and Children New York and White Plains Hospital, White Plains N Y

EDWIN ALLEN LOCKE Ph B A M, M D
Formerly Clinical Professor of Medicine Harvard Medical School Chief Fourth Medical Service Boston City Hospital Chief of Staff Boston Sanatorium Director of Health at Williams College Williamstown Mass

ROBERT F LOEB M D
Lambert Professor of Medicine College of Physicians and Surgeons Columbia University Associate Attending Physician Presbyterian Hospital Associate Attending Physician Neurological Institute New York

WARFIELD THEOBALD LONGCOPE A B M D, LL D, D Sc
Professor of Medicine Johns Hopkins Medical School Physician in Chief Johns Hopkins Hospital Baltimore Md.

CYRIL MITCHELL MacBRYDE A B M D
Assistant Professor of Clinical Medicine Washington University School of Medicine Director Metabolism Division Barnes Hospital St Louis Consulting Physician St Louis City Hospital St Louis Mo

GEORGE M MACKENZIE A B M D
Physician in Chief Mary Imogene Bassett Hospital, Cooperstown New York Director Otsego County Laboratories Oneonta and Cooperstown N Y

HUBERT MANN A B M D
Attending in Cardiology Beth David Hospital Associate Cardiologist Beth Israel Hospital New York

HARRISON S MARTLAND A B M D
Chief Medical Examiner of Essex County N J, Pathologist to City Hospital Newark N J Professor of Forensic Medicine New York University College of Medicine New York

EDWARD H MASON Ph B M D C M F R C P (Can)
Associate Professor of Medicine McGill University Physician Royal Victoria Hospital Montreal Canada

KENNETH ROSE McALPIN A B M A M.D
Assistant Professor of Clinical Medicine Columbia University Assistant Attending Physician Presbyterian Hospital New York City Consulting Hematologist, Nassau Hospital Mineola, New York

WILLIAM S McCANN A B M D D Sc (Hon) F A C P
Dewey Professor of Medicine University of Rochester School of Medicine and Dentistry Physician in Chief Strong Memorial and Rochester Municipal Hospitals Rochester N Y

WILLIAM J McCONNELL B S M D
Director Industrial Health Section Metropolitan Life Insurance Company New York

JOHNSON McGUIRE B S M S M D
Associate Professor of Medicine University of Cincinnati Attending Physician Cincinnati General Hospital Cincinnati O

RUSTIN McINTOSH A B, M D
Carpentier Professor of Pediatrics Columbia University Director of Pediatric Service Babies Hospital New York

CHARLES FREMONT McKHANN M D F A C P
Professor of Pediatrics and Communicable Diseases University of Michigan Medical School Professor of Maternal and Child Health University of Michigan School of Public Health Pediatrician in Chief University Hospital Ann Arbor Michigan

JAMES SOMERVILLE McLESTER, A B., LL D., M D
Professor of Medicine University of Alabama, Physician in Chief Hillman Hospital Birmingham Ala

J H MEANS M D., F A C P
Jackson Professor of Clinical Medicine Harvard University and Chief of Medical Services Massachusetts General Hospital Boston Mass

HENRY EDMUND MELENEY B A., M D
Herman M Biggs Professor of Preventive Medicine College of Medicine New York University New York

KARL F MEYER Ph D M D
Director Hooper Foundation for Medical Research and Professor of Bacteriology University of California Chairman Department of Bacteriology University of California, San Francisco and Berkeley California

WILLIAM SHAINLINE MIDDLETON M D
Professor of Medicine and Dean of the University of Wisconsin Medical School Madison Wisconsin

T GRIER MILLER A B M D
Professor of Clinical Medicine University of Pennsylvania Medical School Assistant Chief of Clinic and Chief of the Gastro-intestinal Section Medical Clinic University of Pennsylvania Hospital Consultant Physician to the Friends the Abington Memorial the Chestnut Hill and Philadelphia General Hospitals Philadelphia, Pa

GEORGE R MINOT A B., M D S D F R C P (Edin) F R C P (Lond)
Nobel Laureate in Physiology and Medicine Professor of Medicine Harvard University Director Thorndike Memorial Laboratory and Visiting Physician Boston City Hospital Member Board of Consultation Massachusetts General Hospital Consulting Physician Peter Bent Brigham and Beth Israel Hospitals Boston Mass

A GRAEME MITCHELL, M D
Late B K Rachford Professor of Pediatrics College of Medicine, University of Cincinnati Medical Director and Chief of Staff of the Children's Hospital of Cincinnati Director of the Children's Hospital Research Foundation Director of Pediatric and Contagious Services in the Cincinnati General Hospital, Cincinnati O

HUGH J MORGAN B S M D
Professor of Medicine Vanderbilt University School of Medicine Physician-in-Chief Vanderbilt University Hospital Nashville Tenn

RALPH S MUCKENFUSS M D
Director Bureau of Laboratories Department of Health Foot of East 15th Street, New York

ALTON OCHSNER M D
William Henderson Professor of Surgery and Head of the Department of Surgery School of Medicine, Tulane University Director of Section on Surgery Ochsner Clinic Senior Visiting Surgeon and Head of the Tulane Surgical Unit, Charity Hospital Senior Surgeon Touro Infirmary New Orleans La

BERNARD SUTRO OPPENHEIMER A B., M D
Clinical Professor of Medicine Columbia University New York City Consulting Physician Mt Sinai and Montefiore Hospitals New York Mt Vernon Hospital, Mt. Vernon N Y

WALTER LINCOLN PALMER, B S., M S M D Ph D., F A C P
Professor of Medicine, University of Chicago Chicago Ill

WALTER WALKER PALMER M D
Bard Professor of Medicine Columbia University Director of Medical Service Presbyterian Hospital New York

JOHN RODMAN PAUL, M D
Professor Preventive Medicine Yale University School of Medicine Associate Physician New Haven Hospital New Haven Conn

JAMES EDGAR PAULLIN A B M D LL D
Professor of Clinical Medicine Emory University Medical School Attending Physician Emory Division Grady Hospital and Piedmont Hospital Atlanta, G

HENRY PINKERTON S B M D
Professor of Pathology St Louis University School of Medicine St Louis Mo

EDWIN HEMPHILL PLACE M D
Clinical Professor of Pediatrics Tufts Medical School Physician in Chief South Department Boston City Hospital Consultant for Contagious Diseases, Massachusetts General Hospital Massachusetts Eye and Ear Infirmary Massachusetts Memorial Hospitals Boston Floating Hospital Newton Hospital Weymouth Hospital Faulkner Hospital and Carney Hospital Boston Mass., Emerson Hospital Concord Mass

NORMAN PLUMMER M D
Assistant Professor of Clinical Medicine Cornell University Medical College Attending Physician The New York Hospital Associate Attending Physician Bellevue Hospital Consulting Physician Manhattan State Hospital and New York Infirmary for Women and Children New York

LEWIS J POLLOCK M D
Professor of Nervous and Mental Diseases Northwestern University Medical School Attending Neurologist Evanston Passavant Memorial and Wesley Memorial Hospitals Chicago Ill

FRANCIS MINOT RACKEMANN A B M D
Associate in Medicine Harvard University Medical School Physician Massachusetts General Hospital Boston Mass

Deceased

I S RAVDIN M D
Harrison Professor of Surgery and Director of the Harrison Department of Surgical Research School of Medicine University of Pennsylvania Philadelphia Pa

BRONSON SANDS RAY M D
Associate Professor of Surgery Cornell University Medical College Attending Surgeon, New York Hospital New York

HOBART A REIMANN M D
Professor of Medicine Jefferson Medical College Hospital Philadelphia Pa

PAUL REZNIKOFF M D
Associate Professor of Clinical Medicine Cornell University Medical College Associate Attending Physician New York Hospital Visiting Physician Bellevue Hospital Consulting Physician Hackensack (N J) Hospital and Mt Vernon (N Y) Hospital Consulting Hematologist United Hospital Port Chester N Y and Tarrytown Hospital, N Y

HENRY BARBER RICHARDSON A B M D
Associate Professor of Clinical Medicine Cornell University Medical College Visiting Physician New York Hospital Visiting Physician Bellevue Hospital New York

HENRY ALSOP RILEY M A., M D
Professor of Clinical Neurology Columbia University Chief of the West Neurological Service Neurological Institute Attending Neurologist (in charge) First Division Goldwater Memorial (Welfare) Hospital Consulting Neurologist New York Orthopedic Hospital New York Englewood Hospital Englewood N J and Reconstruction Hospital N Y

THOMAS MILTON RIVERS A B M D Sc D
Director Hospital of The Rockefeller Institute for Medical Research New York

LEONARD G ROWNTREE M D
Director Philadelphia Institute for Medical Research Research Clinician Philadelphia General and Presbyterian Hospitals Consultant in Medicine Jewish and Rush Hospitals Philadelphia Pa

WILLIAM THOMAS SALTER, M D
Professor of Pharmacology Yale University School of Medicine New Haven Conn

TRUMAN LAURANCE SAUNDERS A B M D F A C S
Attending Surgeon New York Eye and Ear Infirmary Assistant Professor of Otolaryngology College of Physicians and Surgeons Columbia University New York

WILBUR A SAWYER, M D
Director International Health Division Rockefeller Foundation New York

WALTER FRANK SCHALLER M D
Clinical Professor of Medicine (Neuropsychiatry) Stanford University School of Medicine San Francisco Calif

*ANDREW WATSON SELLARDS A. M., M D
Late Richard Pearson Strong Associate Professor of Tropical Medicine Schools of Medicine and Public Health Harvard University Consultant in Tropical Medicine Massachusetts General Hospital Boston Mass

GEORGE CHEEVER SHATTUCK M D
Clinical Professor of Tropical Medicine Harvard Medical School and Harvard School of Public Health Consultant in Tropical Diseases Boston City Hospital Attending Specialist in Tropical Medicine United States Marine Hospital Boston, Mass Consultant in Tropical Diseases Massachusetts General Hospital

JAMES STEVENS SIMMONS M D Ph D Sc D., D P H
Brigadier General Army of the U S., Director Preventive Medicine Division Office of The Surgeon General U S Army

CHARLES H SLOCUMB B S., M S M D
Consulting Physician in Division of Medicine The Mayo Clinic Assistant Professor in Medicine The Mayo Foundation for Medical Education and Research, Graduate School University of Minnesota

DAVID T SMITH A B M D
Professor of Bacteriology and Associate Professor of Medicine Duke University School of Medicine Durham North Carolina

H JOCELYN SMYLY M A M D B Ch., F R C S (I)
Professor of Clinical Medicine Cheeloo University School of Medicine, Tsinan, Shantung China Attending Physician University Hospital Tsinan Shantung China

HARRY C SOLOMON M D
Professor of Psychiatry Harvard Medical School Director Boston Psychopathic Hospital Visiting Neurologist, Beth Israel Hospital Associate Neurologist, Massachusetts General Hospital Boston Mass

TOM DOUGLAS SPIES A B., M. D
Associate Professor of Medicine College of Medicine University of Cincinnati Cincinnati Director Nutrition Clinic, Hillman Hospital Birmingham Alabama

THOMAS P SPRUNT A B., M D
Associate in Medicine The Johns Hopkins University Clinical Professor of Medicine and Acting Head of Department of Medicine The University of Maryland Baltimore Md

WENDELL JOHNSON STAINSBY B A., M D C M
Director Department of Medicine George F Geisinger Hospital Danville Pa

* Deceased

EUGENE A STEAD Jr M D
Professor of Medicine and Chairman of the Department Emory University School of Medicine Co-Chief of Medical Service Grady Memorial Hospital Atlanta, Georgia.

LEWIS D STEVENSON M D
Associate Professor of Neuropathology Cornell University Medical College Associate Professor of Neuropathology New York University, New York

HAROLD J STEWART A B M A., M D
Associate Professor of Medicine Cornell University Medical College Attending Physician The New York Hospital New York

RALPH G STILLMAN M D
Assistant Professor of Medicine (Clinical Pathology) Cornell University Medical College Clinical Pathologist, New York Hospital New York.

JOSEPH STOKES Jr., M D
William H Bennett Professor of Pediatrics School of Medicine University of Pennsylvania Philadelphia, Pa.

ERNEST B STRUTHERS B A., M D., D P H (Toronto) D T M and H (Eng)
Dean of Medicine Cheeloo University School of Medicine Chengtu Szechuan China Attending Physician, University Hospital, Tsinan Shantung, China

CYRUS C STURGIS B S M D
Professor of Internal Medicine Director Simpson Memorial Institute Chairman of Department of Internal Medicine University of Michigan Ann Arbor Mich

HOMER FORDYCE SWIFT Ph B M D Sc D
Member Rockefeller Institute for Medical Research New York Physician to the Hospital of The Rockefeller Institute for Medical Research New York

V P SYDENSTRICKER, B A., M A., M D
Professor of Medicine University of Georgia School of Medicine Physician in-Chief University Hospital, Augusta, Ga

WILLIAM H TALIAFERRO S B., Ph D
Eliakim H Moore Distinguished Service Professor of Parasitology Chairman of the Department of Bacteriology and Parasitology and Dean of the Division of the Biological Sciences University of Chicago Chicago Ill.

WILLARD O THOMPSON B A., M D
Associate Professor of Medicine University of Illinois College of Medicine Associate Attending Physician, Presbyterian Hospital Chicago Ill

WILLIAM S TILLETT M D
Professor of Medicine New York University College of Medicine Director Third Medical Division of Bellevue Hospital New York

THOMAS BOURNE TURNER, B S M D
Professor of Bacteriology Johns Hopkins School of Hygiene and Public Health Lecturer in Medicine Johns Hopkins Medical School Formerly Staff Member International Health Division of the Rockefeller Foundation and Clinical Director Jamaica Yaws Commission Jamaica, B W I

CECIL JAMES WATSON M D Ph D
Professor of Medicine and Director of the Division of Internal Medicine University of Minnesota, Chief Medical Service University of Minnesota Hospital Minneapolis Minn

ISRAEL S WECHSLER, M D
Clinical Professor of Neurology Columbia University Attending Neurologist and Chief of Service The Mount Sinai Hospital Consulting Neurologist, Montefiore Hospital and the Rockland State Hospital New York

ALEXANDER ASHLEY WEECH M D
Professor of Pediatrics College of Medicine University of Cincinnati Medical Director The Children's Hospital Cincinnati, O

SOMA WEISS M D
Late Hersey Professor of the Theory and Practice of Physic Harvard University Physician in-Chief Peter Bent Brigham Hospital Boston Mass

ALLEN O WHIPPLE M D Sc D
Valentine Mott Professor of Surgery Columbia University Director of Surgical Service Presbyterian Hospital New York

PAUL DUDLEY WHITE A B M D
Lecturer in Medicine Harvard Medical School Physician Massachusetts General Hospital Boston Mass

JOHN C WHITEHORN M D
Henry Phipps Professor of Psychiatry and Director of the Department of Psychiatry Johns Hopkins University Psychiatrist in-Chief Johns Hopkins Hospital Baltimore, Md

FRED WISE, M. D
Clinical Professor of Dermatology and Syphilology New York Post Graduate Medical School and Hospital of Columbia University Attending Dermatologist, Montefiore Hospital Chief of Clinic Skin and Cancer Unit of the New York Post Graduate Hospital Attending Dermatologist Reconstruction Hospital Consulting Dermatologist and Syphilologist, Beth El and St Joseph's Hospitals New York

* Deceased

SIMEON BURT WOLBACH M D
Shattuck Professor of Pathological Anatomy Harvard Medical School Pathologist to Peter Bent Brigham Hospital Pathologist in Chief Children s Hospital Consulting Pathologist, Boston Lying in Hospital Free Hospital for Women and Harvard Cancer Commission Boston Mass

W BARRY WOOD Jr A B., M D
Professor of Medicine Washington University Physician in Chief Barnes Hospital St Louis Mo

ROLLIN TURNER WOODYATT M D
Clinical Professor of Medicine Rush Medical College of the University of Illinois Attending Physician the Presbyterian Hospital Chicago Ill

JOHN B YOUMANS B A., M S., M D
Professor of Medicine and Director of Postgraduate Instruction Vanderbilt University School of Medicine, Visiting Physician Vanderbilt University Hospital Nashville Tenn

PREFACE TO THE SIXTH EDITION

The Sixth Edition of the Textbook of *Medicine by American Authors* makes its appearance with extensive changes in both text and format For example, it contains a number of new articles on subjects not covered in previous editions

Virus Pneumonia	Dr Russell L Cecil
Salmonella Suipestifer Infection	Dr Charles A Janeway
Friedlander s Bacillus Infections	Dr Maxwell Finland
Hirudinea	Dr Ernest Carroll Faust
Contact Dermatitis	Dr Harry L Alexander
Aviation Medicine	Dr Alvan L Barach
Seasickness and Air Sickness	Dr Alvan L Barach
Undernutrition	Dr Cyril M MacBryde
Pathologic Physiology of Circulatory Failure and Cardiac Pain	Dr Eugene A Stead Jr
Circulatory Collapse and Shock	Dr Eugene A Stead Jr
Rheumatic Heart Disease	Dr Clarence E de la Chappelle
Senile Osteoporosis	Dr Walter Bauer
Treatment of Infections with Penicillin	Drs Donald G Anderson and Chester S Keefer

In addition to these new topics the present edition contains the following new treatises *on subjects previously covered*

Measles	Dr Charles F McKhann
Varicella	Dr Joseph Stokes Jr
Smallpox	Dr Joseph Stokes Jr
Vaccinia	Dr Joseph Stokes Jr
Poliomyelitis	Dr John R Paul
Erysipelas	Dr Henry M Dawson
Septicemia	Dr Chester Scott Keefer
Focal Infection	Dr Russell L Cecil
Tetanus	Dr Warfield M Firor
Bacillus Coli Infection	Dr Charles A Janeway
Tularemia	Dr Karl F Meyer
Haverhill Fever	Dr W J Stainsby
The Mycoses	Dr David T Smith
Relapsing Fever	Brig Gen James Stevens Simmons A U.S
Weil s Disease	Dr W Barry Wood Jr
Diseases due to Animal Parasites	Dr Ernest Carroll Faust
Sarcoidosis	Dr William S Middleton
Milk Sickness	Dr Russell L Cecil
Miliary Fever	Dr Russell L Cecil
Opium Intoxication	Dr Lawrence Kolb
Cocaine Intoxication	Dr Lawrence Kolb
Diseases of the Intestines	Dr Walter L Palmer
Appendicitis	Dr I S Ravdin
Intestinal Obstruction	Drs Alton Ochsner and Michael E DeBakey
Intestinal Neoplasms	Drs Alton Ochsner and Michael E DeBakey
Affections of the Mesentery	Drs Alton Ochsner and Michael E DeBakey
Cardiac Arrhythmias	Dr Harold J Stewart
Diseases of the Motor Tracts	Dr Samuel B *Hadden*
Paralysis Agitans	Dr D Denny Brown
Convulsive States	Dr William G Lennox
Mental Disorders	Dr John C Whitehorn

Short introductory chapters have been added to most of the larger sections of the book It is hoped that these introductions will prove of value as condensed statements of the general physiologic principles underlying the diseases included in the section The following introductory chapters appear for the first time in this edition

Introduction to the Rickettsial Diseases	Dr S B Wolbach
Introduction to Pneumococcal Infections	Dr Russell L Cecil
Introduction to Deficiency Diseases	Dr John B Youmans
Introduction to Diseases of Metabolism	Dr William T Salter
Introduction to Diseases of the Digestive System	Dr Walter L Palmer
Introduction to Diseases of the Blood	Dr W B Castle
Introduction to Diseases of the Cardiovascular System	Dr Robert L Levy
Introduction to Diseases of the Ductless Glands	Dr Fuller Albright

Another new feature of the book which will be appreciated by all students and practitioners of medicine is a list prepared by Dr Ralph G Stillman of normal values for the commoner laboratory tests With the great multiplicity of tests now in use it becomes more and more difficult to keep normal values in mind For the convenience of the reader Dr Stillman's contribution has been placed at the end of the book immediately preceding the section on treatment of infections with penicillin

In the present edition particular attention has been given to the section on Diseases of the Cardiovascular System The material has been rearranged and several new chapters have been added The editor is grateful to Dr Robert L Levy for valuable suggestions in connection with this section and for discriminating editorial work on the galleys

Because of present day interest in tropical medicine the idea of grouping all tropical diseases together in one section of the book was seriously considered However after further consideration it seemed wiser for teaching purposes to retain the present etiological arrangement

In the Fifth Edition the editor for the first time introduced illustrations into the text This innovation has proved so popular that the number of illustrations in the present edition has been increased

In the Sixth Edition the text has been rearranged in double columns a format which should add greatly to the convenience and comfort of the reader While the page itself has been only slightly enlarged the thickness of the book has been greatly reduced thereby The editor hopes that these changes will be acceptable to teachers students and practitioners who make frequent use of the book

It is a matter of deep regret to have to report the death of eleven contributors Dr Kenneth D Blackfan Dr C Macfie Campbell Dr Raymond L Ditmars Dr Walter W Hamburger Dr Dean Lewis Dr Frederick T Lord Dr A Graeme Mitchell Dr Walter L Niles Dr Joe Harold St John Dr Andrew Watson Sellards and Dr Soma Weiss The editor greatly laments the passing of these distinguished physicians who by their zealous cooperation have contributed so much to the success of the book

In planning the Sixth Edition the editor invited Dr Soma Weiss late Hersey Professor of the Theory and Practice of Physic at Harvard University to act as co editor During the short time of his service Dr Weiss contributed many valuable suggestions and criticisms and his untimely death was a grievous loss to the editor and publishers

The editor is very happy to announce that the present edition of the Textbook is being translated into Spanish and Portuguese The translations should be in print shortly after the appearance of the new edition in English

The preparation of what might be called a war time edition of the Textbook has been no easy task Many contributors are in the service of the Army and Navy and dispersed over the United States and various foreign countries One revised article came all the

was from Chengtu China The overworked professors of medicine who have remained on duty at home must have found it more difficult than ever to prepare adequate revisions of their manuscripts Many thanks to all for such splendid cooperation!

Special acknowledgments are due to Dr Alice Childs and Mrs Natalie J Hoyt for their assistance in proof reading and general editorial work

THE INFECTIOUS DISEASES*

VIRUS DISEASES

INTRODUCTION

INFECTIOUS diseases are caused by certain kinds of active agents or their toxins Such agents are divided into the following groups Protozoa fungi bacteria spirochetes rickettsiae and viruses The diseases of man that are known to be caused by or that are strongly suspected of being caused by viruses are measles German measles mumps fever blisters herpes zoster varicella smallpox, vaccinia rabies psittacosis common cold influenza, St Louis type of encephalitis Japanese type B encephalitis epidemic encephalitis equine encephalomyelitis epidemic pleurodynia lymphocytic choriomeningitis poliomyelitis lymphogranuloma inguinale Australian X disease louping ill Rift Valley fever foot and mouth disease yellow fever pappataci fever dengue fever, warts and molluscum contagiosum

The nature of viruses is not definitely known At present however three groups of ideas seem to cover the possibilities (1) The smallest viruses *e g* the viruses of foot and mouth disease and poliomyelitis may be inanimate incitants of disease transmissible in series Stanley believes that the virus of tobacco mosaic is a nucleoprotein and reports that he is able to obtain it regularly in crystalline form His work is significant and if his interpretations of it are accepted progress will have been made in regard to the nature of certain viruses (2) The medium sized viruses as exemplified by the etiologic agents of yellow fever and fever blisters may represent forms of life unfamiliar to us (3) The virus of vaccinia might well be a minute living autonomous organism or a midget in the microbial world provided the elementary bodies which are infectious and are composed of protein fats carbohydrates and ash represent nothing but individual units of the virus Regardless of the nature of viruses it is accepted that they are smaller than ordinary bacteria and that none of them has been cultivated in the absence of living cells Therefore dead or alive they may be considered as obligate parasites

That the viruses are exceedingly small and that they have not been shown capable of multiplication in the absence of living cells are not sufficient reasons for considering the variety of diseases caused by them as possessing pathologic changes in common Indeed one is repeatedly asked Why are smallpox poliomyelitis mumps and warts diseases with exceedingly diverse clinical pictures grouped together? It is believed that viruses are intimately associated with the cells injured by them and that they multiply or are regenerated within such cells As a consequence of this intimate association viruses exert upon the tissues of their host a decided influence which results in hyperplasia or necrosis In the past pathologists devoted most of their attention to inclusion bodies and inflammation and considered them of prime importance in virus diseases Inclusion bodies are of great significance but they do not occur in all virus diseases Inflammation is seen in most virus maladies but it is nothing more than a secondary phenomenon appearing in the wake of cellular destruction While inclusions are important and inflammation regularly occurs in virus maladies hyperplasia hyperplasia accompanied by necrosis and

* See pages 1532–1536 Treatment of Infections with Penicillin

necrosis the primary pathologic phenomena of virus diseases are common to all characterize them, and logically permit of their segregation, in spite of diverse clinical pictures into the same group of diseases

Most virus diseases are followed by a permanent immunity which is not the rule in bacterial maladies There are exceptions *e g* common colds and fever blisters While there is no general agreement regarding the cause of the lasting immunity many are inclined to believe that repeated contacts with certain viruses the intimate type of parasitism observed in virus maladies or the prolonged, possibly persistent sojourn of some viruses in infected hosts account for the phenomenon

As a rule once signs and symptoms of infection have become manifest specific serum therapy is of no value in virus diseases This is readily understandable in the light of the fact that viruses intracellularly situated are not affected by antibodies and that by the time signs of disease are obvious most, if not all of the susceptible cells that are going to be involved have already been entered

The etiologic agents of virus diseases are smaller than ordinary bacteria appear to be obligate parasites are intimately associated with the cells stimulated or destroyed by them frequently cause inclusion bodies in affected cells usually induce a lasting immunity, and are not harmed by antisera once they have become *intracellularly* situated In view of these facts viruses have been separated from other and better known infectious agents and to the initiate the term *virus* carries as much significance as does the word *bacterium* Consequently the expressions *virus of smallpox* and *Virus variolae* are just as specific in their designation as are the expressions *bacillus of typhoid* and *Bacillus typhosus*

THE COMMON COLD

(*Acute Coryza*)

Definition —The common cold or acute coryza, is a catarrhal inflammation of the upper respiratory tract which results from infection by a filtrable virus or microorganisms, and perhaps from allergic and metabolic derangements not yet well understood Such terms as acute rhinitis 'acute pharyngitis acute laryngitis or tracheitis are often employed to designate the region chiefly affected by the disease

Etiology —The communicability of many catarrhal disorders of the upper respiratory tract indicates the presence of an infective agent but cultures of the nasopharyngeal secretions of patients with colds usually reveal organisms indistinguishable from those found in the nose and throat of healthy individuals The commonest of these are various strains of staphylococcus streptococcus pneumococcus *Micrococcus catarrhalis* and influenza bacillus It is improbable that any of these well known bacteria are the usual inciting agent of the common cold Frequently during the early stages of the disease micro organisms of all kinds are strikingly few and it is only after several days that one or more types of pathogens appear in large numbers in the exudate

In recent years it has been shown by numerous observers that in the nasal secretions of many persons suffering from a fresh cold there is an ultramicroscopic agent which when instilled into the nostrils of normal individuals reproduces the disease Dochez and his co workers have succeeded in cultivating this agent in embryonic tissue media and have indicated that it should be classified among the filtrable viruses Most colds occurring in epidemic form are probably caused by a virus or group of viruses

Following an initial injury of the epithelium bacteria transmitted with the virus or bacteria already present in the respiratory tract assume the role of secondary invaders and may give rise to further symptomatology Small outbreaks of colds are sometimes caused by micro-organisms capable of invading the healthy mucous membrane in the absence of a concurrent virus infection It is not unlikely that the mucus and nasopharyngeal secretions in which the causative agent of colds is disseminated are factors in the epidemiology of the disease for it has been shown that the presence of these materials lowers the natural resistance of the tissues to bacterial invasion

Unaccustomed exposure of the body to cold and the wearing of wet shoes and clothing often precipitate colds Observations made in isolated communities indicate however, that physical exposures and hardships do not *per se* induce coryza unless an agent of infection is also present It is well known that general immunity may be depressed when the body is subjected to sudden temperature changes Furthermore in man chilling of the skin brings about prompt vasomotor reactions in the nasopharynx accompanied usually by ischemia and cooling of the mucous membranes These changes are temporary in the normal subject but in persons prone to catching cold the reaction is said to be sluggish and prolonged It is assumed by most observers that there is a local injury of the tissues and disturbances in the nasal secretions during these episodes which promote infection by pathogenic agents present in the upper respiratory tract Irritants and specific antigens may act similarly but vasomotor disturbances may be induced not only by allergens in the air or food or injected vaccines but may represent a local reactivity in the nasopharynx to systemic derangements affecting vascular tone through physiologic imbalances in the vegetative nervous system Hence the factors of constitution fatigue and emotional strain may be of etiologic importance in certain instances

Many persons have structural abnormalities or foci of chronic infection in the upper respiratory tract such as hypertrophied adenoids nasal polyps or chronic sinusitis where pathogenic bacteria are harbored and normal drainage is disturbed Such persons are not only victims of epidemic coryza but also develop colds when local resistance is impaired by any of the factors mentioned above

Thus it may be seen that the common cold is probably not a clinical entity but comprises a group of different affections The epidemic form may result from primary bacterial invasion but in most instances is due to an ultramicroscopic agent Many are produced by environmental or constitutional factors which lower resistance and allow the common pathogens normally harbored in the upper respiratory tract to invade the mucous membranes

Morbid Anatomy —The characteristic lesion of the common cold is a catarrhal inflammation of any part of the upper respiratory tract or paranasal sinuses The process often begins at a focal area and spreads as the causative agent and irritating bacterial substances are disseminated through the network of lympathics beneath the epithelial surface The local reaction frequently stimulates a vasodilatory reflex which increases the engorgement of the spongy tissues of the nose

The mucous membrane is red and thickened and is covered by an excess of seromucoid secretion that becomes purulent in the later stages Microscopic examination shows little except hyperemia and edema of the tissues and, in the later stages of the inflammatory process an increase of wandering cells Necrosis and desquamation of the epithelial cells follow the initial inflammatory process

The systemic reactions that frequently accompany coryza result from absorption of toxic products from the diseased area

Epidemiology —Diseases of the upper respiratory tract are often highly communicable and may spread readily among the members of a locality Persons with fresh colds transmit the infection most readily At times however the disease seems limited to a single individual and is not contracted even by those in close contact with the patient Both epidemic and sporadic types are much more common during the colder months of the year They are especially numerous in the autumn late in September or during October in midwinter during Janu

ary and February, and again in the spring usually in April This seasonal variation does not depend entirely upon weather conditions as is popularly supposed for the periodicity and severity of colds have been found strikingly similar in various regions irrespective of climatic differences Perhaps the factor of greatest importance is the change to indoor crowding during the winter months especially in schools Under conditions such as these the virulence of infecting agents may be greatly enhanced as they are transferred rapidly from one nonimmune subject to another Infection, once established is spread by sneezing coughing expectoration and blowing the nose all conspicuous features of colds The incubation period of coryza is highly variable Symptoms appear within twelve to ninety six hours after exposure to a coryza of the infectious type Other varieties may be precipitated within a few hours after chilling

Immunity may persist for weeks or months following a coryza Persons complaining of frequent colds usually suffer reinfection from a chronic focus in the sinuses or tonsils

Symptoms —The onset of coryza is usually marked by sensations of burning or itching at the primary site of invasion This is generally in the posterior nares but may be in any portion of the upper respiratory tract In about 30 per cent of cases the inflammation remains localized but in many instances the nose pharynx larynx trachea and paranasal sinuses become involved

At the height of the disease patients are quite dejected and uncomfortable Often they complain of chilly sensations and vague aching in the back and extremities The conjunctivae are suffused the nasal mucosa is red and swollen the nostrils are partly or completely occluded and from them pours continuously a watery discharge which causes much sniffing and blowing of the nose Areas of excoriation appear at the nasal orifices and around the mouth Headache and dull pain in the face and back of the nose are common and are aggravated by the inspiration of air The senses of smell taste and hearing are often impaired The voice becomes husky and muffled marked hoarseness indicates laryngeal involvement The tongue is dry and coated Swallowing and opening the mouth may be painful or difficult Nonproductive coughing is often the most distressing symptom with tracheitis it is associated with a sensation of tightness and soreness behind the sternum The lymph nodes near the angles of the jaw and in the neck may be swollen and tender Constitutional symptoms usually appear early, and vary extremely in severity even during a single epidemic They are not in proportion to the extent or appearance of the lesion in the nasopharynx In severe infections prostration is striking Often there is an elevation of temperature (100°-102° F) Digestive disturbances such as constipation diarrhea anorexia abdominal cramps and nausea are not uncommon especially in some epidemics

The symptoms may last a few days or many months Relapses are especially common seven to twelve days after the initial attack Bronchial involvement and pyogenic infections of the sinuses and middle ears run a tedious course As recovery from the cold progresses congestion gradually diminishes and the secretions become scanty and more purulent During convalescence there may be weakness loss of weight nervousness and insomnia Arthralgia neuralgia and cutaneous hyperesthesia are often troublesome late manifestations

Diagnosis —Typical coryza offers a few diagnostic difficulties Certain specific diseases such as *measles diphtheria scarlet fever pertussis* and *typhoid fever* may be accompanied by catarrhal symptoms at the onset and are consequently mistaken for infections of the upper respiratory tract until more characteristic features develop

Grippe and influenza are closely allied to the common cold The terms are frequently loosely employed to indicate any upper respiratory infection accompanied by toxic symptoms In the same outbreak all gradations between grippe and a mild congestion of the nasopharynx can be observed Recent work indicates that epidemic influenza is caused by a specific virus pathogenic for ferrets and white mice Further studies are necessary to determine whether there is a relationship of this virus to that producing the common cold

A mild or aborted cold is easily confused with noninfectious hyperemia of the nasal

mucous membranes due to such causes as local irritants drugs allergic reactions and various vasomotor phenomena Even with a careful history definite diagnosis may be impossible

Prophylaxis —Measures to prevent colds are of various types The most effective perhaps is reducing to a minimum contact with crowds and infected individuals Strict *isolation* is obviously impossible except for invalids and very young children

The use of germicidal aerosols such as propylene glycol vapor for sterilizing the air of rooms where crowding is prevalent offers the possibility of eventually controlling respiratory infections Prophylaxis of this type is however still in the experimental stage

Spraying and *gargling* with antiseptics are usually ineffectual because it is impossible to free the mucous membranes of bacteria by this method *Irrigations* are of value only when abnormalities in the nose or throat impair the natural mechanisms of elimination In such cases only the blandest solutions should be employed

Vaccines are of limited value Controlled statistics indicate that volunteers inoculated subcutaneously with stock bacterial vaccine or given a polyvalent vaccine orally develop colds about as frequently as those receiving inert material For patients however who suffer from repeated reinfections because of a chronic focus in the respiratory tract vaccine therapy is rational The attempts to immunize against the virus causing coryzas have thus far been unsuccessful Usually infected *foci should be removed surgically* Children especially have fewer colds after *tonsillectomy* or *adenoidectomy*

Exposure to chilling and *out-of-door hardship* are sometimes recommended to increase resistance to respiratory diseases Fresh air minimizes the chance of infection but probably does not affect the susceptibility of the individual Colds are as common among robust athletes as among individuals leading sedentary lives Experience shows that ample clothing dry warm shoes and moderate exercise are better prophylactic measures than most hardening procedures

Patients subject to frequent colds often find relief by seeking semitropical climates during the winter months

Reports on ultraviolet radiation and vitamin feedings do not indicate a prophylactic value

Treatment —The treatment of colds consists mainly in the *relief of symptoms* as they arise Patients are usually more comfortable in bed although in most instances they prefer to continue their daily occupation Rest should be made imperative if the temperature rises above 100° F or if there is evidence of such formidable diseases as diabetes nephritis rheumatic fever cardiac lesions or pulmonary infections *Isolation* is desirable as it protects others and minimizes the opportunity of acquiring secondary infections during a phase of increased susceptibility The body especially the feet should be kept warm and dry Smoke cold damp air and other irritants should be avoided Any simple diet is suitable An occasional saline cathartic is indicated even when the bowels are active

Striking relief from malaise and aching is afforded by some of the *coal tar derivatives* Phenacetin (5 grains 0.3 Gm) with soda bicarbonate (15 grains 1 Gm) every three hours is a well known combination An excellent grippe capsule contains

Codeine sulfate	grain 1/4	015
Acetylsalicylic acid	grains v	.3
Phenacetin	grains ij	12
Caffeine citrate	grain ss	03

If discomfort is marked one of these may be given as often as every three hours

Measures to promote sweating and vasodilatation also add to the comfort of the patient Hot foot baths and warm drinks are *often used to supplement analgesics such as* Dover s powders (10 grains 0 6 Gm) or whisky

Medication should be instituted as early as possible to diminish the hyperemia of the mucous membranes Spraying with 1.5 per cent ephedrine hydrochloride in normal saline every three hours is recommended if the drug is well tolerated Inhalation of Benzedrine from a patented inhaler is more convenient for the ambulatory patient These drugs not only relieve the stuffiness in the nostrils and help maintain adequate drainage from the nose but perhaps shorten the attack by diminishing the initial injury to the mucous membranes that follows intense congestion

Patients with laryngitis or tracheitis

should rest the voice Violent coughing should be controlled by codeine in sufficient doses if the usual emulcent or expectorant cough mixtures prove ineffectual Relief is also afforded by inhalations from a vessel containing about a pint of hot water and a teaspoonful of compound tincture of benzoin or oil of pine

Tender glands in the neck are best treated by intermittent application of ice bags

Pain and tightness under the sternum is benefited by counterirritants such as turpentine liniment mustard plasters, or flaxseed poultices

The possibility of acute pyogenic complications such as sinusitis or otitis media must constantly be considered Many of these subside spontaneously with conservative treatment therefore operation in most cases should be deferred until the need for surgical drainage is imperative

The oral administration of the sulfonamides which is not indicated in the treatment of acute colds may be beneficial when secondary bacterial infections develop Reports are favorable on the local use of these drugs such as 5 per cent suspensions of microcrystalline sulfathiazole in acute colds as prophylaxis against pyogenic complications but further confirmation is needed

Rest with a vacation is important after a severe cold It is unwise to permit patients to return to full activity in a weakened condition Nourishing food sunlight and avoidance of fatigue are essential Tonics especially those containing nux vomica or cod liver oil are beneficial

INFLUENZA

Definition—Influenza is a highly contagious specific infectious disease which occurs most characteristically in epidemic and pandemic outbreaks during which it spreads with extraordinary rapidity The principal manifestations are sudden onset with fever marked prostration severe aching pains in the back and extremities conjunctival injection and a rapidly progressive inflammation of the respiratory mucous membrane It is self limited and of short duration Rarely serious in its uncomplicated form it often becomes so because it predisposes to frequent and highly fatal secondary infections of the lungs

History.—Although there is little doubt that influenza is a disease of great antiquity its authentic history according to Leichtenstern begins with the European epidemic of 1510 Since that time numerous epidemics have been recognized and recorded in all parts of the world At least eight great pandemics with their preceding and succeeding epidemics have occurred—1580 1729–30 1780–82 1830–33 1836–37 1847–48 1889–92 and 1918–20

Epidemiology—The history of influenza shows that great pandemics sweep the world at irregular intervals and that less severe more circumscribed epidemics occur fairly frequently during interpandemic periods

Pandemic influenza typically exhibits *three major waves* separated from each

other by a distinct interval of several months The *first wave*, though it affects great numbers of persons is relatively mild and is not attended by a high incidence of complications Its duration in a single community may vary somewhat in different localities but is always short—three to six weeks The *second wave* also attacks great numbers of persons but is more severe than the first and is accompanied by a high incidence of complications especially pneumonia with a resultant excessive mortality Like the first wave its onset is explosive in nature, reaching its peak in two to three weeks but the period of decline may be somewhat less rapid and is not infrequently interrupted by a period of recrudescence The *third wave* develops more slowly, the peak is not sharp and the period of decline is less rapid While the number of persons attacked is somewhat less complications are frequent and severe This alteration in the characteristics of the successive waves of pandemic influenza may be due in part to a partial immunity of those previously attacked in part to variations in the prevalence and kind of secondary infections which so frequently complicate the disease

The *morbidity* from influenza during pandemic outbreaks is very high, the best statistical studies placing it between 200 and 400 per 1000 While people of all ages are susceptible the *highest* incidence is between the ages of five and forty

Influenza which occurs in more or less localized outbreaks during interpandemic periods is now distinguished from pandemic influenza by designating it *epidemic influenza* It has occurred in many parts of the world at irregular intervals of one to four years since the last pandemic ended in 1919 It differs from pandemic influenza in being less severe and in having a lower attack rate usually between 10 and 20 per cent

The exact relationship between epidemic and pandemic influenza is still uncertain Lack of complete knowledge concerning the immunologic relationships of different strains of influenza virus and lack of opportunity to investigate the etiology of pandemic influenza by the methods which have proved successful in epidemic influenza make it impossible to answer this problem at the present time

In addition to the recurrent cyclic nature of both pandemic and epidemic influenza the most characteristic epidemiologic features are the explosive nature of the outbreaks the rapidity of spread the high attack rate and the relatively short duration of the individual waves All of these features may be explained by the combination of a fairly general susceptibility a short incubation period and the brief self limited course of the uncomplicated disease Other contributing factors may be found in the fact that many who are attacked continue to work and thus spread the disease and in the ready transmissibility of primary respiratory infections The rapidity of spread is further influenced in any given area by the rapidity of the existing means of travel and the extent of human intercourse being more rapid in thickly settled communities less so in sparsely populated districts Presumably dissemination occurs directly from person to person through contact and droplet infection by talking coughing or sneezing

Etiology —The epidemiologic and clinical features of pandemic and epidemic influenza suggest that it is caused by an easily transmissible infectious agent possessing a high degree of primary pathogenicity for man The theory that *Hemophilus influenzae* is the specific cause of influenza which was generally accepted until the pandemic of 1918 has since been abandoned in favor of the view that the primary incitant is a filtrable virus Convincing evidence in support of this latter view in so far as epidemic influenza is concerned was provided in 1933 by Smith Andrewes and Laidlaw who succeeded in isolating a filtrable virus from patients with influenza by inoculating ferrets intranasally with filtrates of throat washings from early cases The infection was transmitted from ferret to ferret and subsequently to mice These observations have been amply confirmed by Francis Burnet, Smorodintseff and others from many parts of the world Though it was believed at first that all strains of virus from various parts of the world were serologically identical it would now appear that not only different epidemics but even the same epidemic may be caused by immunologically distinct races of influenza virus At least two which are

designated influenza A virus and influenza B virus respectively, have been identified and doubtless others exist While the foregoing studies have dealt only with epidemic influenza it seems probable that they will be found applicable to pandemic influenza Whether or not pandemic influenza will be found to be due to a strain of virus different from those so far isolated or to be a symbiotic infection comparable to swine influenza (Shope), only future study can determine

Bacteriology —Many bacteria play a significant role as secondary invaders especially in pandemic influenza The most frequent is *Hemophilus influenzae* which is commonly found in large numbers in the secretion of the respiratory tract during life At necropsy it is frequently encountered in the pus from infected sinuses and in the exudate throughout the bronchi and bronchioles It is less often found in the parenchyma of the lung and only rarely invades the pleura pericardium or blood Other important secondary invaders are *Pneumococcus Streptococcus haemolyticus* and *Staphylococcus aureus* Organisms less frequently met with are *Streptococcus viridans Staphylococcus albus Micrococcus catarrhalis Friedlander's bacillus* and *Meningococcus*

Morbid Anatomy —So far as is known simple uncomplicated influenza causes no characteristic changes which serve to differentiate it from other catarrhal inflammations of the respiratory mucous membrane In severe rapidly fatal cases of influenza with pneumonia there is in addition to the rhinitis and pharyngitis an intense tracheitis and bronchitis often hemorrhagic a very marked bronchiolitis with epithelial necrosis and serosanguineous exudate in the lumen peribronchiolar and hemorrhagic pneumonia marked alveolar edema and emphysema with a characteristic hyaline fibrin lining the distended air spaces and little or no pleural involvement In cases in which secondary infection dominates the picture the pulmonary pathology is complex Noteworthy characteristics referable to infection with *Hemophilus influenzae* are bronchitis purulent bronchiolitis often leading to bronchiectasis and peribronchiolar and atrial pneumonia while those referable to the pyogenic cocci are interstitial and confluent lobular pneumonia often attended by necrosis abscess formation and a marked tendency to organizing pneumonitis Mediastinitis and empyema frequently occur when hemolytic streptococci are present (Opie, *et al* Winternitz, *et al*)

The *paranasal sinuses* often show intense *inflammation* of their mucous membranes and contain purulent exudate Hemorrhages may occur in the skeletal muscles especially in the *rectus abdominis* also in the pericardium spleen kidneys adrenals testes and cerebrum *Interstitial emphysema* of the pleura lungs mediastinum and neck is sometimes found Other lesions which may be found at autopsy are referred to below under Complications

Symptoms —The *incubation period* lasts from one to three days usually about forty to forty eight hours The *onset* is sudden with fever chilly sensations and prostration usually accompanied by catarrhal symptoms referable to the nose the pharynx or the trachea Depending upon the severity of the infection the subsequent course of the disease is so variable that it can best be described by division into types

Simple Form without Complications —Simple uncomplicated influenza comprises more than 95 per cent of the cases during the first wave of a pandemic 70 to 90 per cent in the subsequent waves and is the form commonly encountered in epidemic influenza The *onset* is usually sudden without a period of invasion The initial symptoms are chilliness extreme general malaise and severe aching pains throughout the whole body but especially in the back and extremities *A varying degree of prostration* sometimes leading to complete collapse is almost invariably present Severe headache is common Stupor or delirium occasionally occurs The temperature rises rapidly ranging from 100° to 106° F in most cases being between 102° and 106° F The pulse rate varies between 80 and 100 and the respiration rate is slightly accelerated The patient appears listless the face and often the neck and upper thorax are deeply flushed the conjunctivae are injected the pharyngeal mucosa is intensely congested The soft palate often exhibits a punctate erythema sometimes a petechial rash Shortly after onset coryza begins or sore throat due to *the pharyngitis or soreness* behind the

manubrium sterni with a dry irritative cough due to tracheitis Whether the respiratory symptoms are an essential phenomenon of influenza or are a secondary manifestation is not entirely certain They are unquestionably present in the vast majority of patients and have been considered by most clinicians to be an integral part of the disease Epistaxis is fairly frequent occurring in 10 to 15 per cent of the cases Gastro intestinal symptoms are usually slight nausea vomiting and diarrhea being rare except in children At this age gastro intestinal disturbances frequently dominate the picture

The *subsequent course* of the disease is brief The fever persists for from one to five days in the majority of cases from two to four days It is often diphasic in character The respiratory symptoms become more marked usually being well developed at the end of twenty four hours They may remain localized in the nose the pharynx or the trachea but more commonly spread rapidly throughout the respiratory tract, sometimes as far down as the large bronchi The progress of respiratory infection is marked subjectively by sensations of irritation stinging and a feeling of tightness A thin mucoid exudate appears which later may become mucopurulent With the development of tracheitis there is a sense of burning and tightness beneath the sternum accompanied by a harassing cough The sputum which at first is scanty mucoid and sometimes streaked with blood later becomes mucopurulent Laryngitis may develop Examination of the chest reveals little abnormality except when involvement of the large bronchi gives rise to scattered rhonchi and sibilant rales

Examination of the *blood* shows a leukopenia in most cases during the acute stage although in the mildest cases the white count may be normal or even slightly elevated Although opinion differs as to the nature of the leukopenia it would appear to be predominantly a lymphopenia Blood cultures are usually sterile The *urine* frequently shows a febrile albuminuria

Recovery is prompt the temperature usually falling by rapid lysis occasionally by crisis Although convalescence is rapid in most of the simple cases it may be attended by a prolonged period of depression and asthenia In the absence of secondary complications *relapses* do not occur and there are no fatalities in this type of the disease

Simple Form with Complications—Between the simple uncomplicated form of influenza and the severe pneumonic form there is a type which is prolonged by the development of a purulent bronchitis or sinusitis or both The bronchitis begins insidiously without any prominent symptoms to mark its onset About the third or fourth day when recovery from the primary disease is expected the patient begins to cough more frequently and to raise increasing amounts of mucopurulent sputum This may be quite abundant and is often somewhat nummular in character It frequently shows the presence of *Hemophilus influenzae* together with one or more other organisms such as *Pneumococcus Streptococcus* or *Micrococcus catarrhalis* Examination of the chest reveals numerous coarse medium and fine moist rales scattered throughout the lungs usually most numerous over the lower lobes The percussion note breath and voice sounds and vocal and tactile *fremitus* remain normal A moderate elevation of temperature rarely above 101° F and of irregular character usually persists for a few days or a week There is little or no increase in the respiration or pulse rates and cyanosis is unusual in the absence of bronchopneumonia In many cases a persistent cough due to chronic bronchitis continues for weeks Sometimes a mild degree of chronic bronchiectasis results Mucopurulent sinusitis affecting any or all of the paranasal sinuses may be a distressing complication accompanied by severe headaches prolonged fever and prostration Otitis media also occurs more commonly in children

This form of the disease comprises 10 to 15 per cent of the cases in the second and third pandemic waves and is also not infrequently encountered in epidemic influenza

Pneumonic Form—During the second and third pandemic waves from 5 to 15 per cent of all patients develop pneumonia In a large majority of instances the pneumonia is caused by a mixed infection of the bronchi and lungs with *Hemophilus influenzae* and one or more associated organisms the most common being *Pneumococcus Streptococcus*

haemolyticus and *Staphylococcus aureus* Of the pneumococcus infections 85 to 90 per cent are caused by the ordinary mouth pneumococci In some cases *H influenzae* alone is found In a few instances of fulminating rapidly fatal infection no organisms have been found The pathology and to some extent the clinical course of the pneumonia is determined by the bacteria concerned (Opie *et al*) It is clear that pneumonia in general should be regarded as a complication of primary influenza even though a limited number of cases may occur in which the disease is pneumonic from the outset and fatal before secondary organisms invade the lungs

Clinically the pneumonic form may be divided into three types which it is true overlap in any large series of cases These are (1) a fulminating rapidly fatal form in which pneumonia is present from the outset (2) a progressive form in which on the second to fourth day the signs of pneumonia begin to develop without the appearance of any decline in the fever (3) a late form in which after apparent recovery from the primary influenza pneumonia suddenly supervenes on the fourth to tenth day after onset

In the first form which is comparatively rare and ordinarily occurs only during the rise and height of the second pandemic wave the onset in addition to the symptoms of simple influenza is accompanied by great respiratory distress intense cyanosis and signs of rapidly developing hemorrhagic edema of the lungs The condition is very alarming Patients thus affected may die within twenty four to forty eight hours

The second and third forms differ only in time of onset of the pneumonia and may be discussed together The primary influenza is the same as in the simple form The onset symptoms physical signs and course of the pneumonia are very variable ranging all the way from those of a mild bronchopneumonia with limited pulmonary involvement from which there is prompt recovery in four or five days with defervescence by lysis or crisis to those of a rapidly progressive coalescing pneumonia with fatal outcome In some cases the picture is that of lobar pneumonia in others there is a long drawn out course due to necrotizing or organizing processes Certain features deserve special consideration In many cases the areas of pneumonia are isolated and deep seated so that in spite of the severity of the condition the typical signs of consolidation do not appear until comparatively late The involvement is nearly always bilateral The signs usually appear first over the lower lobes and are apt to vary greatly from day to day as the disease progresses The temperature curve is very irregular The pulse except during the last thirty six hours in fatal cases is apt to be slow in proportion to the temperature The respiratory rate varies with the severity of the disease Cyanosis which is a prominent feature is largely of the lilac or heliotrope type and indicates insufficient oxygenation of the blood as it passes through the lungs Early pleurisy except in hemolytic streptococcus infections and in the rapidly coalescent cases is uncommon The character of the sputum varies It may be scanty bloody and mucoid or profuse purulent salmon pink or yellowish green the latter type being associated with an extensive bronchiolitis or bronchiectasis The leukopenia of the primary influenza frequently continues throughout the course of the pneumonia especially in the severe cases A relative polycythemia often occurs when the disease is rapid and severe the red blood cell count sometimes reaching 8 000 000 per cubic millimeter Blood cultures are rarely positive except as a terminal event the serious features of the disease probably being due to toxemia and anoxemia rather than to septicemia Recovery is frequently delayed by the formation of abscesses and by failure of resolution Sudden death occasionally takes place during apparent recovery Convalescence is often prolonged Chronic bronchitis and bronchiectasis are frequent sequelae

Complications —Influenza predisposes to secondary infection with a variety of organisms Whether this is preponderantly due to lowering of general resistance by the extreme prostration of the disease and the inhibition of leukocytic defense or to a destruction of local resistance against bacterial invasion by profound injury to the respiratory mucosa or to a combination of

both factors is uncertain It seems most probable that both are concerned At any rate, complications are numerous and varied and in large part determine the mortality of the second and third pandemic waves The most frequent and important complications are acute sinusitis otitis media with or without acute suppurative mastoiditis purulent bronchitis and bronchiolitis bronchiectasis and pneumonia The pneumonia itself may be complicated by the development of pulmonary abscesses especially when *Streptococcus haemolyticus* or *Staphylococcus aureus* are present. Empyema is common in the streptococcus cases and usually begins relatively early in the course of the pneumonia Mediastinitis pneumothorax and interstitial emphysema may occur

Erythema, simple purpura and subcutaneous abscesses occasionally appear Herpes is infrequent Rupture of the rectus abdominis muscles with hematoma has been noted in a considerable number of cases Epistaxis is frequent hemoptysis and hemorrhage from the bowel much less so The circulatory system is not commonly affected but pericarditis endocarditis and thrombophlebitis are occasional complications A postinfluenzal bradycardia sometimes develops Tympanites is frequent in the toxic pneumonic cases and a moderate icterus may develop Peritonitis is a rare complication Arthritis and osteomyelitis have been observed with influenza Nephritis is rare Meningitis hemorrhagic encephalitis and multiple neuritis occasionally occur Transient postinfluenzal psychoses are seen

The *commonest sequelae* are chronic bronchitis chronic bronchiectasis and pulmonary fibrosis These conditions may persist throughout life and not infrequently lead to a mistaken diagnosis of pulmonary tuberculosis

Diagnosis —There is no single pathognomonic feature upon which a diagnosis of influenza may be made During pandemics however the diagnosis is not difficult in the majority of cases The sudden onset of a febrile attack with severe prostration and aching pains in the back and legs which are out of proportion to the catarrhal symptoms together with the flushed face injected conjunctivae intensely congested pharynx and a leukopenia are the characteristic manifestations When there are numerous other cases the foregoing features warrant a diagnosis of influenza During interpandemic periods the diagnosis is even more difficult unless substantiated by isolation of the virus or by appropriate immunologic tests which demonstrate an increase in specific antibody titer during convalescence The recognition of complications depends upon the characteristic symptoms and physical signs of the condition in question Whenever the fever persists for more than four days a complication should be suspected and carefully looked for

Prognosis.—The prognosis of simple uncomplicated influenza is excellent In cases with the less serious complications such as sinusitis laryngitis and bronchitis the prognosis is also good and recovery takes place unless further complications develop Purulent bronchiolitis and bronchiectasis however may result in chronic pulmonary disease which persists for years with periods of exacerbation and remission With the onset of pneumonia the prognosis becomes serious the mortality rate varying all the way from 15 to 60 per cent under varying circumstances The degree of cyanosis and the rate of respiration are probably the two most important prognostic signs A persistent progressively increasing cyanosis particularly of the heliotrope type and a progressively increasing tachypnea nearly always indicate a fatal outcome Even when patients appear to be doing well a sudden change for the worse may supervene at any time so that prognosis should be cautious until convalescence is well established In pregnancy the prognosis is always serious the mortality high

Prophylaxis —While there is at present no specific prophylaxis of proved value for preventing influenza in man, it has been shown that ferrets and mice can be successfully immunized against the experimental disease and that protective antibodies develop in the blood serum of human subjects following subcutaneous injection of influenza virus vaccine There is also some evidence that a high titer of specific humoral antibodies is one expression of relative immunity to the natural disease and that vaccination with influenza virus vaccine enhances resistance Further study of this problem is

necessary however, before vaccination can be recommended

Complete isolation is a preventive measure of proved though little practical value except under very exceptional circumstances Individuals should avoid contact with known cases during epidemic outbreaks

Treatment —There is no specific cure for influenza The most important forms of treatment are (1) absolute confinement to bed *from the onset of the disease until convalescence is well established* and the danger of complications is past (2) administration of large quantities of fluid (3500 to 5000 cc daily) during the febrile period (3) isolation from sources of secondary infection and the practice of medical asepsis by those coming in contact with the patient If these are rigidly adhered to the incidence of complications may be greatly reduced During the acute period the diet should be light For the headache an ice cap should be employed and if necessary aspirin 0.3 to 1 Gm (5 to 15 gr) may be given It is also of value for relief of the general aches and pains If there is sleeplessness Dover s powder 0 6 Gm (10 gr) may be used A simple enema should be given to relieve constipation The use of an inhaling mask is of value in allaying the irritation of the respiratory mucous membranes Five to 10 drops of the following mixture should be placed on the sponge at intervals as necessary menthol 1 part, creosote 1 part chloroform 1 part

The treatment of the complications does not differ from the treatment of pneumonia sinusitis etc in general and is presented in the appropriate chapters

DENGUE

Definition —Dengue or breakbone fever' is an acute specific febrile disease caused by a filtrable virus and transmitted by mosquitoes of the genus *Aedes* It is characterized by sudden onset with fever and prostration and by intermission of fever on the third or fourth day with recurrence after eighteen to thirty hours A rash appears during the period of apyrexia or with the second rise in temperature The duration is seldom longer than seven days

History.—The first known epidemics of dengue occurred in Egypt and Java in 1779 a year later Philadelphia experienced the severe outbreak described by Rush It is possible that a disease recorded in Seville during the seventeenth century was dengue During the past one hundred and fifty years many widespread epidemics have occurred in the southern United States and in many other areas

Incidence —Dengue occurs wherever the mosquito *Aedes aegypti* abounds and climatic conditions are suitable for the survival of the virus in this vector It is endemic in the tropics and mildly so in certain subtropical and even temperate regions During the past twenty years there have been severe epidemics in the Southeastern and Gulf states of the U S in Australia Egypt and in Greece Between epidemics sporadic cases are occasionally seen

Mode of Transmission —In 1903 Graham suggested that dengue was transmitted by mosquitoes and suspected *Culex fatigans* Four years later Ashburn and Craig working in the Philippines demonstrated that the causative agent could be transmitted by blood that it was filtrable and that a mosquito was the vector though they erroneously implicated *Culex quinquefasciatus* In 1916 Cleland Bradley and McDonald in Australia showed that *Aedes aegypti* could transmit the disease but that Culicine mosquitoes could not be infected This observation was confirmed by Koizumi and his collaborators and by American investigators in

the Philippines The latter group demonstrated that *Aedes albopictus* could also be infected A mosquito having once ingested the blood of a person with dengue is able to transmit the disease during the remainder of its life though Blanc and Caminopetros found that the virus became noninfective when mosquitoes known to carry it were kept at temperatures below 20° C (64 4° F) This observation probably explains the rapid subsidence of epidemics of dengue with the advent of cool weather

Period of Infectivity —While Blanc and Caminopetros were able to transmit dengue with intravenous injections of patients blood taken during the first five days of illness Simmons St John and Reynolds showed that for mosquitoes to become infected it was necessary for them to ingest blood during the first forty eight hours They also proved that there is then a period of extrinsic incubation or presumable multiplication of the virus in the mosquito of at least nine days usually twelve before the vector is able to infect by its bite

Immunity —An attack of dengue produces transient immunity probably for not longer than five years in most individuals perhaps as long as ten in some Major epidemics in certain localities have occurred at five-year intervals affecting from 50 to 60 per cent of the population on each occasion No protection is afforded by the injection of convalescent serum or blood nor is filtered infectious plasma or serum rendered avirulent by treatment with immune serum Second and third attacks are apt to be mild and somewhat atypical

Etiology —The specific causative factor of dengue is a filtrable virus capable of passing Chamberland candles L_2 and L_3 It resists refrigeration for at least fifty four days and drying for at least ten months Koizumi was able to transmit the disease by injection of as little as 0 00005 cc of blood drawn during the first febrile period Experimental animals do not show fever or symptoms after inoculation but Blanc and Caminopetros observed that the blood of guinea pigs was infectious for human subjects five days after the injection of virulent blood or serum They also produced a transient asymptomatic and afebrile carrier state in some nonimmune human subjects

Epidemiology —Noteworthy epidemics of dengue occur when there is a coincidence of free propagation of *Aedes aegypti* with waning immunity of the human population Such conditions exist when after a period of five or more years there are unusual warmth and abundant rainfall during the late summer and early autumn in almost any locality between the parallels 32° 50 North and 23° 25′ South *Aedes aegypti* is thoroughly domesticated and able to breed in very small amounts of water so that the innumerable containers present in any center of population offer optimum facilities for oviposition Since dengue is mildly endemic throughout its distribution and it has been shown that some infected individuals remain free from symptoms an excessive number of mosquitoes soon become infected An epidemic of dengue spreads with rapidity comparable only to pandemic influenza In Athens 80 to 90 per cent of the population were ill during the epidemic of 1928–29 and in the 1934 epidemic in Florida at least 30 per cent of the permanent residents of Miami were infected While some epidemics depend on the local introduction of infected persons or mosquitoes it is likely that the unrecognized endemic disease is of paramount significance The epidemiology of dengue is important since it reflects the potential distribution of yellow fever *Aedes aegypti* being the vector of the virus of both diseases

Morbid Anatomy —Few valid observations on the pathology of dengue are available since death in uncomplicated cases is very rare Bensis saw five autopsies during the 1928–29 epidemic in Greece The gastrointestinal tract showed petechial hemorrhages probably related to the exanthem There were nonspecific parenchymatous changes in the myocardium skeletal muscles and liver The kidneys showed glomerulitis and interstitial infiltration with leukocytes The meninges were congested and the brain showed proliferation of glial cells and some leukocytic infiltration The lymph nodes were moderately enlarged as was the spleen

Symptoms and Signs —The incubation period has been shown to be from four to ten days Onset is abrupt with severe headache often localized behind the eyes pain on moving the eyeballs lumbar backache and extreme prostration Occasionally there is rigor

and children may have convulsions Loss of the sense of taste and complete anorexia are usual nausea and vomiting frequent and constipation almost constant The temperature rises in a few hours to 102° to 104° F and may reach 106° F Relative bradycardia is the rule and some patients have heart rates as low as forty Systolic blood pressure is depressed often below 100 mm of mercury and the pulse may be dicrotic During the first few hours all the larger joints particularly those of the knees hips and vertebrae become intensely painful so days, there is then rapid defervescence accompanied by profuse sweating and often diuresis sometimes there is epistaxis or diarrhea All symptoms are greatly improved during the period of intermission which is most often of twenty four hours duration There is then a second rapid rise in temperature to 102° to 103° F all symptoms recur and the characteristic rash appears This is almost always scarlatiniform but varies in distribution Typically it appears first over the knees ankles and elbows which may show periarticular swelling The entire

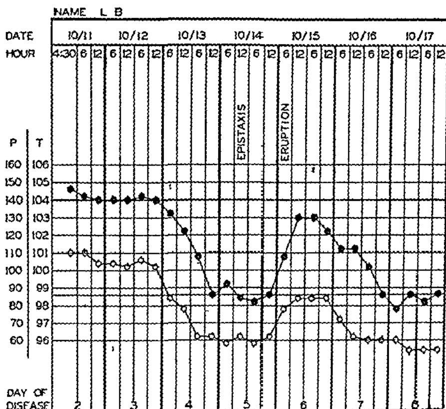

Fig 1 —Temperature chart of a patient with dengue

that motion is almost impossible though passive movement may be tolerated A transient pale pink macular rash is often seen at the onset The face is flushed the conjunctivae and sclerae are much congested and mild injection of the pharynx is common Some glandular enlargement is present in about three fourths of the cases the epitrochlear inguinal and posterior cervical nodes being most frequently palpable The spleen is not infrequently felt just below the costal border and is quite soft Fever and symptoms persist for three sometimes four body except the face may be involved or there may be a patchy distribution over the trunk and the flexor surfaces of the extremities The palms and soles are bright red and often so edematous that flexion of the hands and feet is painful Some patients have marked pruritus before or with the eruption The rash and symptoms persist until final defervescence which occurs with great regularity after two days on the sixth or seventh day of illness Desquamation is frequent Certain cases are atypical in that the second febrile period does not occur Convalescence

is apt to be slow, bradycardia hypotension and asthenia may persist for weeks

The blood constantly shows leukopenia due to granulocytopenia The leukocyte count is usually between 2000 and 6000 with 20 to 45 per cent of granulocytes Many of the polymorphonuclear cells show toxic or degenerative changes vacuolization, pyknosis and fragmentation of nuclei basophilic granulation and vacuoles in the cytoplasm are common Coles has described minute round and oval diplococcoid bodies in the red cells which are demonstrable by prolonged staining with dilute Giemsa Their significance is not established

The urine is often scanty and concentrated from vomiting and inadequate intake of fluids Albuminuria and cylindruria are seldom more than fever would explain

Complications—Bleeding from the nose gastro intestinal tract and uterus may occur and seem to have been unusually common in the Greek epidemic Heart failure and acute renal insufficiency have been observed in patients with arteriosclerosis The syndrome of neurocirculatory asthenia is a rather frequent sequel to dengue

Diagnosis—Illness beginning suddenly with headache muscle and joint pains nausea and fever during a time when *Aedes* mosquitoes are abundant should suggest dengue At the onset it may be mistaken for influenza malaria or measles In areas where typhus or yellow fever are endemic it may be confused with them Seen first after the exanthem has appeared it may suggest scarlet fever In unvaccinated individuals smallpox may be suspected The course of the illness speedily differentiates influenza and measles malaria can be excluded by examination of the blood Leukopenia and bradycardia rule out typhus even before the characteristic remission of fever and eruption Yellow fever can be eliminated by absence of icterus and albuminuria Lack of angina of marked cervical adenitis and of leukocytosis serves to differentiate dengue from scarlet fever but occasionally smallpox cannot be excluded until the eruption appears

Prognosis—Death from uncomplicated dengue probably occurs in less than 1 case in 10 000 In severe epidemics the rate may far exceed this because of prevalence of the disease among the higher age groups with advanced vascular disease of the brain, heart or kidneys

Prophylaxis—Personal prophylaxis includes avoiding *Aedes* mosquitoes and the use of mosquito nets and repellants All patients should be kept under close mosquito nets and all measures taken to destroy mosquitoes and their breeding places on the premises Communities should make every effort to eliminate actual and potential breeding places Blanc and Caminopetros were able to produce apparent immunity by vaccination with infectious serum treated with bile

Treatment—This is entirely symptomatic Pain is often mitigated by codeine 0 033 Gm (grain 1/2) and acetylsalicylic acid 0.333 Gm (grain v) given as frequently as necessary codeine 0 066 Gm (grain i) or morphine 0 008 Gm (grain 1/8) given hypodermically may be required when nausea is severe atropine should be combined with these Ice caps to the head cold sponges or packs and cool rectal irrigations give some relief from fever For nausea chloretone 0.2 Gm (grain iii) repeated each hour for three or four doses is often effective though the favorite remedy is calomel 0 006 Gm (grain 1/10) every half hour until the bowels move Diet should be liquid and fluids forced to tolerance Fluids must be given parenterally when nausea prevents an adequate intake by mouth During convalescence the diet should be increased slowly Rest is essential and should be prolonged in the cases of elderly individuals

YELLOW FEVER

Definition —Yellow fever is an acute disease caused by a filtrable virus and characterized in severe and typical cases by sudden onset prostration, moderately high fever a pulse rate slow in relation to temperature vomiting of altered blood albuminuria and jaundice It occurs in certain tropical and subtropical countries but epidemics have extended far into the Temperate Zone during warm seasons There is but one yellow fever by clinical or immunologic criteria but the disease is classified on an epidemiologic basis as aegypti transmitted when the virus is transferred by the mosquito *Aedes aegypti* the long recognized vector under urban and some rural conditions or as jungle yellow fever when it occurs in a forest or jungle environment in the absence of that mosquito The aegypti transmitted disease involves man primarily and is perpetuated in the recurring cycle man aegypti man but jungle yellow fever is presumably an infection of unidentified animals which is occasionally transferred to man particularly to young adult males who work in the forest by jungle mosquitoes or other arthropods not yet fully identified

Etiology —The cause of yellow fever is one of the smaller filtrable viruses By filtration through gradocol membranes its diameter has been found to lie between 17 and 25 millimicrons It can be preserved for at least ten years by thoroughly drying virus containing serum in the frozen state sealing in glass and storing at low temperatures

The virulence of yellow fever virus on account of differences in tissue affinity is of two kinds which may vary independently Viscerotropism in yellow fever virus gives the power to attack principally the liver kidneys and heart while neurotropism results in damage to the nervous system When both properties are present the virus is pantropic and it is in this form that it is found in nature No purely viscerotropic strain of yellow fever virus has been produced in the laboratory but strains acquire a heightened neurotropism and almost entirely lose their viscerotropism during long passage through mice by intracerebral inoculation Both virulences have been greatly reduced by prolonged cultivation in certain types of tissue culture

Man is highly susceptible to the natural pantropic virus and the characteristic lesions of yellow fever in man are due to its viscerotropism Whether the nervous system of man is ever directly involved in natural infections is subject to doubt Some brain symptoms which have been reported may have been due to hemorrhage or a toxic factor The rhesus monkey (*Macaca mulatta*) is even more susceptible than man to pantropic virus and it reacts in a similar way If a rhesus monkey is inoculated intracerebrally with a highly neurotropic strain a severe and usually fatal encephalitis results and there are ordinarily no evidences of viscerotropism Other monkeys are susceptible in varying degrees and many are practically insusceptible Mice especially certain selected laboratory strains are highly susceptible to the neurotropic virulence but insusceptible to the viscerotropic The white rat is insusceptible to both virulences The European hedgehog (*Erinaceus europaeus*) is highly susceptible to both Some other animals show few symptoms but are sufficiently susceptible to permit the multiplication of virus and practically all animals tested are capable of producing protective antibodies if given large inoculations of living virus

In aegypti transmitted yellow fever the mosquito *Aedes aegypti* formerly called the stegomyia transmits the disease by biting a person during the first three or four days of yellow fever the period in which the virus circulates freely in the blood and later biting a susceptible person An interval of from nine to twelve days or more depending largely on temperature must elapse before the mosquito will become infectious through biting but throughout this incubation period the virus in the insect is infective if its body is ground up and injected Much shorter and longer incubation periods in the mosquito have been observed under extremes of temperature in laboratory experiments There is definite multiplication of the virus in the mosquito at favorable temperatures

In jungle yellow fever the virus most probably is transmitted by mosquitoes or other arthropods Under laboratory conditions 17 mosquitoes from various parts of the world in addition to *Aedes aegypti* are capable of transmitting yellow fever by biting These are in Africa *Aedes luteocephalus Aedes stokesi Aedes vittatus Aedes africanus Aedes simpsoni Aedes taylori Aedes metallicus Eretmopodites chrysogaster Mansonia africana* and *Culex thalassius* in South America *Aedes scapularis Aedes fluviatilis Aedes leucocelaenus* and *Haemagogus capricorni* in the East Indies *Aedes albopictus* in Europe *Aedes geniculatus* and in North America *Aedes triseriatus* Specimens of two of these *Aedes leucocelaenus* and *Haemagogus capricorni* wild caught in areas of South America were found to contain yellow fever virus and to be able to infect monkeys by biting Likewise in Africa *Aedes simpsoni* wild caught in the Bwamba forest of Uganda were recently found to contain yellow fever virus It remains to be shown which of the numerous biting insects of the forest play the dominant role in the transmission of yellow fever

Numerous accidental laboratory infections in the absence of aegypti have suggested that man may be infected through contact of the virus with unbroken skin or mucous membranes Experiments with monkeys have shown that pantropic yellow fever virus in blood may pass through unbroken skin and cause the disease Monkeys and mice have been infected by intranasal instillations of neurotropic virus and mice by putting neurotropic virus into the conjunctival sac

Infection with virus of yellow fever is present only in certain parts of the world and is completely absent from many tropical and subtropical countries in which aegypti mosquitoes abound In recent years a world survey of immunity in man against yellow fever was carried out by testing many thousands of blood specimens in mice for their power to protect against yellow fever virus In this way it was shown that immunizing infections with yellow fever virus had been recently occurring in South America and Africa in vast interior areas previously supposed not to be infected The systematic collection and examination of liver specimens in cases of febrile diseases in South America obtained from the cadaver by means of the viscerotome showed that fatal cases of yellow fever were occurring in the region in which immunity had been found Moreover epidemics of jungle yellow fever have recently occurred in the regions of observed

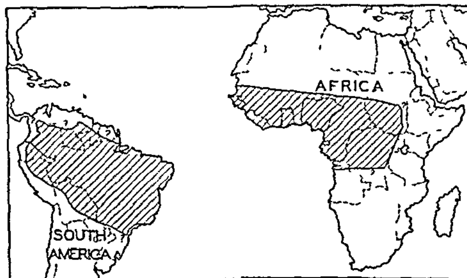

Fig 2—Approximate world distribution of yellow fever immunity (shaded areas) determined by blood tests and based on immunity acquired since 1925 in the Western Hemisphere and within the present generation in the Eastern Within the areas are the two great *endemic regions* all recognized epidemics since 1925 and coastal areas of Brazil freed of yellow fever infection by mosquito control

immunity It is believed that the two vast areas of immunity in South America and Africa contain the endemic regions from which yellow fever escapes from time to time to start urban aegypti transmitted epidemics and to spread through commercial paths Since 1938 no important outbreaks of aegypti transmitted yellow fever have been reported from the Western Hemisphere but epidemics of jungle yellow fever have been observed Epidemics of aegypti transmitted yellow fever occur frequently in West Africa and it is probable that the immunizing infection in Central Africa is similar in its epidemiology to the jungle yellow fever of South America

The knowledge of the etiologic factor in yellow fever has been acquired in several steps In 1881 Carlos Finlay of Cuba announced his unshakable belief that the disease was transmitted by the mosquito now known as *Aedes aegypti* In 1900 and 1901 Reed Carroll Agramonte and Lazear of the United States Army Yellow Fever Commission performed experiments with human volunteers in Cuba and proved that the causative agent was transmitted from man to man by this mosquito and that it could pass through a Berkefeld filter capable of holding back *Staphylococcus aureus* In 1927 Stokes Bauer and Hudson working in West Africa under the auspices of the International Health Division of The Rockefeller Foundation, showed that the common rhesus monkey was susceptible to yellow fever and used it in studying the properties of the virus In 1930 Theiler found out in Boston that the mouse also was susceptible if inoculated intracerebrally In 1931 in New York Sawyer Kitchen and Lloyd commenced vaccinating persons effectively with simultaneous subcutaneous injections of human immune serum and living neurotropic yellow fever virus In 1932 Soper Penna Cardoso Serafim Frobisher and Pinheiro described in Brazil the first epidemic in which it was proved that *Aedes aegypti* was not the transmitting agent thus revealing the existence of jungle yellow fever From 1933 to 1937 in New York Lloyd Theiler and Ricci and Theiler and Smith performed the experiments with yellow fever virus in tissue culture which resulted in the production of a profoundly altered strain 17D low in viscerotropic and neurotropic virulence and suitable for widespread vaccination

Morbid Anatomy—The skin usually has a distinct yellow color, more intense than during life and there may be petechiae or ecchymoses The mouth or nostrils are often stained with vomitus containing altered blood The liver is of normal size or slightly enlarged Its color is brownish yellow which turns usually to chamois color when the blood is drained out The stomach commonly contains varying amounts of brownish black altered blood Such blood may be found in the intestines also Petechiae are often observed in the mucosa of stomach and duodenum The spleen shows little alteration in size or general appearance The kidneys are swollen and pale, and on section the cortex is pale and yellowish The heart is pale and flabby The brain shows little surface change

Under the microscope the most characteristic and striking lesions are those in the parenchymatous cells of the liver There is profound noninflammatory necrosis and fatty degeneration This is most evident in the midzone of the lobule and a band of normal cells is ordinarily seen around the central and portal veins Scattered irregularly among the affected cells are certain ones showing acidophilic coagulative hyaline necrosis (Councilman bodies) Although acidophilic intranuclear inclusions are frequently found in the hepatic cells of experimentally infected monkeys they are rare in those of man The spleen shows degenerative changes which are most prominent in the malpighian corpuscles The kidneys show cloudy swelling necrosis and fatty degeneration of the tubular epithelial cells There is also fatty degeneration of the heart The microscopic lesion found most frequently in the brain is perivascular hemorrhage There is usually no evidence of encephalitis due to the neurotropism of yellow fever virus

Symptoms—The incubation period is commonly between three and six days but may be as long as ten Prodromal symptoms are usually absent and the onset is sudden sometimes with a chill but usually not The outstanding symptoms in the first stage of the disease which lasts two or three days are fever severe headache and backache a varying amount of pain in the legs and

prostration The face is flushed and turgid The eyes are injected and there is photophobia The tongue is pointed and bright red at tips and edges but the dorsum is grayish white Jaundice is usually absent or indistinct in the first stage The temperature and pulse rise abruptly at onset the former ordinarily to between 102° and 104° F., but sometimes higher The pulse rate usually reaches ninety or hundred beats per minute and then falls for a few days more rapidly than would be in proportion to the irregular downward trend of the temperature (Faget's sign) The pulse is full and strong at this stage Epigastric distress and tenderness nausea and vomiting of fluid without blood are common Constipation is the rule The leukocyte count is normal or low at the onset and it falls throughout this stage Albuminuria usually begins on the second day and is definite on the third

The *second stage* begins on the third or fourth day At about this time there may appear the characteristic *remission of temperature* followed by a secondary rise but this remission is often indefinite or absent It may be accompanied by a deceptive temporary improvement In this stage the face becomes pale sometimes with cyanotic tinge The headache and backache cease or diminish Restlessness gives way to lassitude and depression sometimes with mental confusion Jaundice gradually becomes visible There may be petechiae in the skin The gums are often swollen and bleed easily either spontaneously or when pressed from outside through the lip The nose may bleed The dorsum of the tongue becomes increasingly dry and brown The pulse rate falls progressively and may go below fifty This bradycardia is attributed to damage to the sino auricular node Even in otherwise mild attacks there may be marked dilatation of the heart and low blood pressure as evidence of myocardial derangement Vomiting may be frequent and distressing and the vomitus in this stage contains altered blood which settles from the clear fluid as small dark brown flakes (flywings) or masses resembling coffee grounds The leukocyte count reaches its lowest point around 3000 per cubic millimeter on the fifth or sixth day of the attack and then rises rapidly reaching normal early in the convalescence The amount of albumin in the urine rises sometimes to 5 or 6 Gm per liter The urine is acid and highly colored and contains numerous granular casts Late in the disease it may contain bile Fatal cases often exhibit hiccough copious vomiting of altered blood black stools and anuria followed by convulsions or coma Death occurs most commonly from the sixth to the ninth day but rarely a few days later If there is recovery, the temperature is likely to reach normal by the seventh or eighth day Convalescence begins then and progresses rapidly to complete recovery, with disappearance of the albuminuria True relapses probably do not occur Complications are rare A lifelong immunity follows the attack

The majority of all yellow fever cases are mild and show few of the classic symptoms described Frequently the only evident symptoms are a brief and slight fever with headache A peculiarity of yellow fever is the great variation in the degree to which the various organs are attacked With much kidney involvement there may be no heart symptoms and *vice versa* In mild and moderate cases there is frequently little or no albuminuria or jaundice

Diagnosis.—A satisfactory provisional diagnosis may be made on the basis of symptoms in many moderate and severe cases but experienced clinicians have had difficulty in distinguishing yellow fever by that criterion from leptospiral jaundice (Weil s disease) other jaundices or even malaria influenza and dengue The short course of yellow fever and the mildness of the jaundice help to distinguish it from most of the other jaundice diseases Although it takes time and requires the collaboration of a specially qualified laboratory the diagnosis may be settled by either of two standard procedures About 30 cc of blood should be drawn early in the acute disease with precautions for sterility and a similar specimen should be obtained three weeks after onset The sterile serum from each should be sent to a laboratory with facilities for making yellow fever protection tests If the first specimen fails to protect mice against yellow fever virus and the second one does the disease was yellow fever If neither protects or both protect equally the illness was some other disease In taking blood for any purpose during

the acute disease rubber gloves should be worn as the blood of yellow fever is highly infectious for the first three or four days The other method is to draw blood from the vein within the first three days of illness and inject 0 03 cc of the serum intracerebrally into each of six susceptible mice and observe them for two weeks If any one of the mice shows symptoms suggestive of encephalitis its brain should be removed emulsified in physiologic salt solution and injected into six other mice These should be sent to the laboratory in order that the virus may be isolated and identified The former method is usually the more practical For postmortem diagnosis specimens of liver and other tissues should be placed in 10 per cent formalin and sent to the laboratory

Prognosis —The cases clinically recognized and reported in a recent urban epidemic (Rio de Janeiro 1928–1929) showed a fatality rate of 59 per cent and this may be taken as representative Case fatalities ranging from 10 to 85 per cent have been cited however Negroes ordinarily have a lower fatality than whites or Orientals If the numerous mild infections were recognized the reported case fatalities would be much lower

In individual cases the prognosis early in the disease should always be guarded as sudden changes for the worse are not uncommon If symptoms are mild recovery is probable and some severe cases will end favorably but hiccough copious black vomit melena and anuria justify a grave prognosis

Treatment —There is no specific treatment At the beginning the severe headache may require relief with an analgesic The bowels should be cleared with a saline laxative Thereafter enemas should be given as needed The patient should be moved as little as possible and should be kept quiet in bed The heart should be watched If the region is one in which vector mosquitoes exist the windows and doors should be screened and a bed net used The quarters in which infection may have occurred should be disinsectized with an efficient spray to destroy all infective *Aedes aegypti* Food should in general be withheld during the acute disease but citrus fruit juices and alkaline waters such as Vichy or ordinary tap water with added bicarbonate of soda should be given freely in small draughts If vomiting interferes with giving fluids by mouth dextrose in buffered solution may be administered intravenously physiologic salt solution by hypodermoclysis and tap water by rectum If glucose is given 50 Gm in 1000 cc of physiologic salt solution may be administered intravenously three times daily accompanied by thiamine hydrochloride 2 mg ascorbic acid 50 mg and nicotinic acid amide 15 mg These vitamins may be given in the glucose solution or separately by mouth or parenterally To relieve vomiting cracked ice and cocaine hydrochloride 0 016 Gm (¼ grain) may be given by mouth and codeine sulfate 0 032 Gm (½ grain) by hypodermic injection For the fever an ice cap or cold compress may be applied to the head and the body may be sponged with cool water The mouth should be cleansed thoroughly and frequently When vomiting has ceased and the temperature is down feeding may be cautiously resumed beginning with rice water, crumbled egg yolk and chicken broth each with added lactose

For prevention individuals who expect to be exposed when visiting infected countries or investigating yellow fever should be vaccinated with an avirulent strain of living yellow fever virus such as 17D Cities under risk should protect themselves by thorough control of the mosquito vector *Aedes aegypti* by the systematic and efficient methods now available These include districting the community so that a trained inspector with flash light may visit each room in each house of his district and the surrounding premises every week Containers harboring larvae of *Aedes aegypti* should be eliminated mosquito proofed or treated with fuel oil so that they will have to be freed of adherent ova by scrubbing before they are refilled Such measures may be depended on to suppress an epidemic or render a community noninfectible

MEASLES

(*Morbilli Rubeola*)

Definition—Measles is a highly communicable disease of world wide distribution which tends to recur in epidemic form at two to four year intervals Fever cough coryza conjunctivitis and a typical enanthem characterize the period of invasion With the appearance of the eruption there is an exacerbation of the systemic symptoms Defervescence and fading of the eruption occur simultaneously and are usually complete from seven to ten days after the onset of the illness

History—Measles was not clearly distinguished from the other exanthemata until the seventeenth century when Sydenham differentiated the disorder from scarlet fever The observations of Panum on the epidemic in the Faroe Islands in 1846 established the epidemiology of the disease in a manner which renders this work *a classic in its field* Characteristic signs especially the spots which appear on the buccal membranes in the prodromal and early eruptive stages of the disease had *been noted by several investigators* but their pathognomonic significance was recognized and stressed by Koplik in 1896 The transmission of measles by inoculation of the catarrhal secretions of patients to susceptible children was performed in 1758 by Home and was reintroduced in 1842 by Katona Controlled observations on inoculation of susceptible persons with blood of patients ill with the disease were reported by Hektoen in 1905 Anderson and Goldberger in 1910 reported transmission of the disease to the *monkey* No other experimental animal has been consistently found to be susceptible to the disease The value of the use of human immune bodies for the prophylaxis *or for attenuation of* the disease introduced by Cenci in 1905 was established by the observations in 1918 of Chapin and of Nicolle and Conseil

Epidemiology—Measles is of world wide distribution apparently uninfluenced in incidence by climate, race nationality or by social or economic status While sporadic cases may be observed at any time the disease has a striking epidemic recurrence, usually in late winter at intervals of two to four years varying with the size of the community Thus, in large cities epidemics occur at two year intervals while in smaller communities the disease may recur as infrequently as four or five years The *seasonal incidence* in the late winter and early spring months is one of the unexplained features of the epidemiology The disease is extremely communicable due apparently to a uniform susceptibility, to the ease of transmission and to the minute dosage of the virus required to produce infection The disease may occur at any age However the high degree of communicability usually results in its being a disease of early life In urban populations over half of the cases occur in children less than five years of age but during epidemics in areas from which the disease has long been absent elderly patients have been affected Over 95 per cent of adults in *urban populations and* only a slightly lower percentage in rural populations have had the disorder Measles in the pregnant woman is apt to be followed by miscarriage The disease has been observed in the neonatal period usually when the mother is suffering simultaneously from it Most mothers *are immune to measles* however and the infants of these mothers acquire an immunity due to passive transfer of antibodies to the fetus which serves to prevent the development of the disease in the infant up to four or five months of age Although the story is often obtained that a child has suffered from multiple *attacks of measles* it is infrequent that authentic instances of second attacks can be established Immunity following an attack of unmodified measles is usually permanent while the degree of *immunity following* the attenuated form has not been adequately determined

Etiology—The causative agent of measles is presumed to be a filtrable virus However until recent years various investigators have held the view that a streptococcus isolated from the blood or from the secretions of patients with *measles* might be the

etiologic agent Measles has been produced experimentally and by accident in man as a result of the inoculation of blood or secretions of patients with the disease Accurately controlled observations on the transfer of the disease to human volunteers by the inoculation of blood of patients suffering from the disorder were reported by Hektoen in 1905 Inoculation of the *Macaca rhesus* monkey with the blood and with secretions from the mouth and nose of patients with measles has resulted in the production of fever and an eruption in the animal Numerous experiments have been made in other animals but with no satisfactory results In recent years several investigators claim to have cultivated measles virus in the developing chick embryo and the histologic picture of the growth of the virus in the chick s allantoic membranes has been described Rake Shaffer and Stokes have reported cultivation of the virus of measles in chick embryos and thereby to have attenuated the virus so that it produces a milder disease when inoculated into humans The attenuated chick embryo culture virus after nine or more passages is also effective in producing the experimental disease in monkeys The virus so prepared is difficult to maintain requiring special arrangements for storage even at refrigerator temperatures Confirmation of these investigations especially a more extensive experience with inoculation measles and of the immunity resulting from inoculation with the attenuated virus as well as observations to determine whether the attenuated virus will revert in one or two human passages to a more virulent form must be made before inoculation with cultivated virus may be recommended

Dissemination—Measles is apparently transmitted through the secretions from the eyes and the respiratory passages with infectivity highest in the preeruptive stage Direct contact and droplet infection are the usual modes of dissemination although spread by air-borne infection through so called droplet nuclei is possible The virus is thought to be short lived outside the body and not readily transmitted by a third person the rapid spread of the disease is deemed to be due to the high degree of infectivity and the almost complete lack of resistance in individuals who have not previously experienced it Infectivity apparently subsides rapidly after the appearance of the rash and is thought to cease after the rash has begun to fade It is well established that complications of measles other than those specifically due to the virus such as the encephalitis will not spread the disease Thus a postmeasles bronchopneumonia might transmit the secondarily invading organisms but would not be a source of spread of measles The numbers of cases of measles which occur in an epidemic often are quite large so that from 80 to 95 per cent of susceptive individuals in a community will be attacked in a single epidemic Thus unlike certain other communicable diseases in which a few cases suffice to make an epidemic the number of cases of measles in an epidemic in a large community may run into thousands In 1940 276 032 cases of measles with 681 deaths were reported in the United States

Pathology.—The lesion in the skin in measles consists of a proliferative and exudative reaction in the capillaries of the deeper layers of the skin with an extension of the exudate of serum and endothelial leukocytes to the epidermis in the hair sheaths and the sebaceous glands When the rash becomes apparent the lesions have already reached their peak A desquamation in the form of fine branny scales follows measles The Koplik spots observed in the buccal mucosa correspond to the minute early lesions in the epidermis The Koplik spots tend to macerate or become somewhat eroded and lose their characteristic appearance on the second or third day of their presence Occasionally ulcerations of the buccal mucous membrane occur A catarrhal inflammation is observed in the eyes the nose and the mucous membranes of the entire respiratory tract

It is rare that a patient succumbs to uncomplicated measles Most commonly death is due to bronchopneumonia which is not due to the measles virus but to a secondary invader chiefly *Streptococcus haemolyticus* The bronchopneumonias are characterized by interstitial reaction and vascular lesions, are often prolonged and may terminate in chronic pulmonary suppurative processes Encephalitis on the other hand is thought

to be due directly to the measles virus Shaffer Rake and Hodes have added credence to this belief by the isolation of the virus from the brain in a fatal case of measles encephalitis The brain in cases of post measles encephalitis shows edema congestion and small petechial hemorrhages scattered throughout both gray and white matter but predominantly in the white matter of the pons medulla and lower cord On microscopic examination perivascular round cell infiltration is seen together with perivascular demyelinization about the venules of the white matter but relatively little destruction of axones or nerve cells

Symptomatology —The *incubation period* is perhaps more constant in measles than in any other common communicable disease Usually ten to eleven days elapse after exposure before the first symptoms appear while fourteen days pass between exposure and the beginning of the eruption Rarely is an incubation period of less than a week observed and only in cases modified by serum is the incubation period likely to exceed fifteen days

The *period of invasion* sometimes called the *period of catarrh* lasts from the onset of symptoms to the appearance of the eruption It is characterized by fever general malaise lacrimation congestion of the conjunctivae catarrhal signs in the upper respiratory passages and congestion of the mucous membranes of the nose and mouth with the appearance in twenty four to thirty six hours of the typical Koplik spots on the buccal mucous membranes A slight defervescence may occur before the appearance of the eruption Variations of the usual temperature curve occur in the natural course of the disease In some cases there is a steady gradual rise in the temperature with the peak reached at the appearance of the rash in others there is an early rapid rise and a sustained temperature until the rash reaches its fullest extent while in the cases modified through the use of serum the temperature curve is usually lower often not exceeding 100° F

Shortly after the onset of the disease the membranes of the eyes become reddened and swollen accompanied by lacrimation and often photophobia A zone of congestion in the lower eyelids described by Stimson, usually gives way in a day or so to congestion involving the entire conjunctiva There is a seropurulent nasal discharge accompanied by attacks of sneezing or hoarseness and a dry, hacking cough which may persist throughout the course of the illness

The *pathognomonic Koplik spots* in the buccal mucosa are found in about 97 per cent of patients Koplik spots appear most often opposite the first molar teeth or deep inside the lower lip as bluish white specks pin point in size surrounded by a bright red areola They are best seen by bright daylight At first there may be only a few but later they become numerous and coalesce to present a moth-eaten appearance on the surface of the buccal mucosa The importance of Koplik spots lies in the possibility of their early recognition which permits the isolation of the patient two to three days before the rash is evident In addition to the specific lesions the mucous membranes are congested and swollen and bluish red blotches often may be seen on the soft palate The catarrhal symptoms in the prodromal stage of measles may be mistaken for those of any form of acute upper respiratory infection Recognition of the disease is possible however through the observation of the conjunctivitis especially the line described by Stimson and the subsequent appearance of Koplik spots A leukopenia with absolute decrease in the lymphocytes is usually present in the blood at this stage

Occasionally in the period of invasion a *prodromal rash* appears often resembling the rose spots of typhoid but more commonly a blotchy erythema similar to mild drug eruptions or to the early erythema of scarlet fever The prodromal rash is transient disappearing before the typical eruption is evident In the period of invasion the spleen may become palpable

The *period of eruption* begins about fourteen days after exposure three to four days after the onset of fever and two to three days after the appearance of Koplik spots The eruption lasts four to five days but may remain as long as a week The eruption is first noted in the hair line behind the ears on the neck and over the forehead It extends from above downward gradually covering the entire body The lesions first

appear as tiny red papules surrounded by pallid areolae They rapidly enlarge to form dusky red macules which increase in number and become grouped together to form blotchy, irregularly shaped lesions which tend to become confluent especially on the face and on the back With the appearance of the eruption the subjective symptoms usually increase and the temperature rises often as high as 104°–105° F The patient complains of itching and burning and his face is puffy his eyes are swollen and red and there is considerable photophobia The discharge from the nose which has been serous often becomes purulent The cough is frequent harsh and unproductive The patient looks and feels miserable After the eruption has reached its peak a striking improvement takes place The temperature drops rapidly the catarrhal symptoms recede the cough diminishes and in a few hours the patient feels much improved The eruption fades in the order of its appearance Desquamation follows in the wake of the rash as a slight brownish scale bran like in character usually completed in five to ten days

Course Modified by Serum —The incubation period of measles modified or attenuated through the use of serum may be prolonged to as much as seventeen or eighteen days The period of invasion may be characterized by a mild catarrhal reaction of the respiratory passages with few subjective symptoms and without the appearance of Koplik spots The eruption appears as transient spotty scattered erythematous lesions often confined to the face and back The febrile response may be sharp but of short duration or may be more prolonged but low grade lasting throughout the period of invasion or eruption At times the febrile rise may be the only manifestation of the disease

Severe forms of measles have been most frequently encountered in debilitated infants and seldom in older patients except among native populations who have been free of the disorder for many years *Hemorrhagic* or *black measles* is a particularly severe form There is marked hyperpyrexia prostration and signs of shock with the appearance of the eruption purpuric spots develop over the entire body Bleeding may occur from the mucous membranes of the nose or pharynx and there may be bloody stools Rarely a highly fatal toxic form of measles is seen with hyperpyrexia cyanosis and delirium, convulsions stupor or coma appearing rapidly after the onset of the disease

Complications —Measles apparently exerts a temporary depressing effect upon immune responses rendering the patient especially susceptible to secondary infections The disease however also temporarily diminishes allergic reactions Consequently although the list of complications of measles is long allergic responses are seldom among them The catarrhal conjunctivitis pharyngitis, laryngitis tracheitis bronchitis and frequently enteritis should be regarded as part of the disease rather than complications Complications are usually those of infection by the streptococcus the pneumococcus the influenza bacillus and occasionally the staphylococcus Infections of the upper respiratory passages the ears paranasal sinuses the larynx and the lungs are most frequent Complications may appear in any stage of measles but are most likely to develop in the late eruptive stage In contagious hospitals diphtheria was at one time frequently encountered as a complication of measles Tuberculous processes may be aggravated by measles resulting in exacerbation and the reappearance of symptoms of a previously quiescent tuberculosis Laryngitis is a troublesome manifestation even in uncomplicated cases of measles but in the presence of secondary infection may be severe and dangerous Hoarseness and a croupy cough are observed in many children with measles while in more severe forms aphonia cyanosis dyspnea substernal and suprasternal retraction may appear The laryngitis usually subsides when the rash begins to fade but if it persists is indicative of secondary laryngeal infection and may require drastic treatment Bronchitis indicated by cough and often by the presence of ronchi is likewise a characteristic feature of the disease If the finer bronchioles are involved signs may persist for some days after the appearance of the eruption Only a longer persistence with continuation of fever or the spread to the smaller bronchioles with appearance of fine crepitant rales should cause anxiety Bronchopneumonia has been the chief cause of

death Though bronchopneumonia may occur at any age it is most frequently a menace in children less than three years of age and in elderly persons

Measles was in 1917 the largest single cause of death in the United States Army, deaths being due mostly to *secondary bronchopneumonia* The bronchopneumonia usually is noted in the late eruptive stage When the eruption has begun to fade the patient does not improve but continues a febrile course with prostration rapid pulse and respiration and frequently a persistent unproductive cough and cyanotic tinge to the lips and nail beds The febrile response is irregular the temperature may be only slightly elevated or it may be swinging or persistently high The physical signs are usually those of a scattered or diffuse pneumonic process characterized by little evidence of gross consolidation but with numerous patches of fine rales throughout both lungs After the process has been present for some time bronchial breathing and impairment of resonance may be observed The disease may run its course in a week or ten days or may be prolonged lasting three to four weeks It is particularly likely to be followed by sequelae such as empyema unresolved pneumonia suppurative pneumonitis interstitial pneumonitis or bronchiectasis Infiltration of the lungs observed on roentgenograms may be a characteristic part of measles and only larger infiltrations which persist after the fading of the rash should be construed as evidence of bronchopneumonia Lobar pneumonia is rarely seen as a complication of measles

Measles seems especially likely to cause an exacerbation of a latent or suppressed *tuberculous process* Consequently tuberculosis should be suspected in patients with prolonged pulmonary signs or with persistent low grade fever or with the appearance of cervical adenitis of prolonged duration Less commonly seen at the present time generalized miliary tuberculosis tuberculosis of the bones and joints and tuberculous meningitis were once common sequelae The tuberculin test during and for a short time after measles may become negative or less positive than it was before the attack

Otitis media accompanied by pain fever redness and bulging of the ear drum is a common complication particularly likely to develop in a hospital ward *Mastoid* disease and *chronic deafness* are less frequently seen after measles than after scarlet fever With individual isolation of each case of measles, the incidence of otitis media may be greatly reduced

Cervical adenitis frequently follows measles but is usually not severe *Catarrhal conjunctivitis* may follow improper care of the eyes and may result in keratitis chronic ulceration or rarely panophthalmitis

Gangrenous *stomatitis* or *noma* is a sequel to measles which is fortunately rare *Cardiac involvement* endocarditis pericarditis myocarditis and other rheumatic manifestations are infrequent

While most of the sequelae of measles are due to secondarily invading organisms the *encephalitis* which follows measles is probably referable to the virus of the disease itself Encephalitis usually develops in the stage of eruption but is often not recognized until the stage of defervescence. The rash fades but the persistence of fever the stupor the muscular rigidity hypertonicity and often generalized convulsions draw attention to the central nervous system Encephalitis occurs in less than one tenth of 1 per cent of cases of measles No apparent relationship exists between the severity of the measles and the development of encephalitis Spinal fluid in measles encephalitis is clear but under increased pressure The cell count may be normal or there may be a pleocytosis as high as two hundred cells mostly lymphocytes There is increased globulin with a normal amount of sugar The *prognosis* of post measles encephalitis is somewhat better as regards life than that of other forms of neurotropic virus encephalitis but the symptoms of coma and stupor may persist for weeks and be followed by permanent sequelae of weakness spasticity tremors ataxia or mental deterioration *Meningitis* of bacterial origin may occur following measles as a sequel to otitis media mastoiditis bronchopneumonia or tuberculosis Scarlet fever diphtheria varicella or pertussis associated with or following measles has been less frequent with the improved care of patients in communicable disease hospitals The frequency of pertussis epidemics following measles may be related to the ordinary sea-

sonal incidence of these two diseases Ordinarily the urine is normal throughout measles although there may be a febrile albuminuria in patients with high temperatures Occasionally nephritis may follow measles but it is a rare complication Gastro intestinal disorders are relatively common and a simple enteritis is particularly troublesome especially in infancy where a diarrheal disorder may lead to a fatal termination

Differential Diagnosis—In the prodromal stages of measles the diagnosis is made with frequency only during epidemics since the catarrhal symptoms are otherwise not enough to suggest the disease The first pathognomonic sign is the appearance of Koplik spots which may not develop until relatively late in the period of invasion They should be sought in bright daylight in the buccal mucous membrane opposite the molar teeth Rarely they fail to appear in patients who have not received serum while in patients who have received serum it is common for Koplik spots to be absent. The diagnosis of measles in the eruptive stage cannot be made from the appearance of the eruption alone since a skin eruption definitely morbilliform may be seen in rubella in roseola infantum in certain cases of serum disease in sulfonamide reactions and in eruptions following the use of phenobarbital dilantin or nirvanol Eruptions following dilantin or phenobarbital medication may closely resemble measles not only in the appearance of the eruption but in the presence of congestion of the mucous membranes The leukopenia present in the pre eruptive stage and the early stage of eruption of measles is of some value However, roseola infantum the drug rashes and serum sickness may be similarly accompanied by a leukopenia

Rubella usually appears with little in the way of prodromal signs the first symptoms occurring within a few hours of the appearance of the rash During the first day German measles may look like a pale measles eruption However the disorder is more often confused with scarlet fever which it resembles on the second day while on the third day the rash usually fades Catarrhal symptoms are minimal and often absent The suboccipital and posterior cervical lymph nodes are characteristically swollen and somewhat tender German measles lasts three or four days and is seldom followed by desquamation or by pigmentation of the skin

A *scarlet fever* eruption on the extremities may present a blotchy appearance suggesting measles but if one examines the trunk as well as the extremities the characteristic scarlatiniform rash is apparent

Serum disease particularly after injection of large doses of unrefined types of serum may be morbilliform in character Careful inspection of the surface of the body usually reveals at least a few urticarial lesions

The eruption of *roseola infantum* (exanthema subitum) resembles quite closely that of measles but is usually a paler pink and is relatively slight on the face The course of roseola should serve to distinguish it from measles Roseola is characterized by three or four days of fever sometimes swinging but often a sustained temperature of 103°-105° F with little prostration and no localized findings with the possible exception of a slight pinkishness of the ear drums and some injection of the buccal mucous membranes Moderate to marked leukopenia occurs in the disease with white counts often as low as 1800 There are no Koplik spots and the temperature usually comes to normal before the rash appears and remains down throughout the period of eruption

Prognosis—The mortality rates of measles have shown in recent years a steady decline apparently paralleling the improvement in general health among infants and children since it was among debilitated undernourished children often those living in institutions that the mortality rate was high Deaths from measles in infants under six months are rare due to the immunity in this age group The death rate reaches its maximum in the preschool years falling rapidly in later childhood Since the deaths are usually due to the complications of bronchopneumonia laryngotracheobronchitis or enteritis it is obvious that crowding or exposure of one measles patient to another may have a definite influence upon prognosis The deaths from measles bronchopneumonia have been strikingly reduced by the introduction of sulfonamide therapy The influence of measles upon tuberculosis

has also been minimized by the diminution of the numbers of cases of childhood tuberculosis Although it is rare for a person to succumb to uncomplicated measles instances of such deaths have occurred particularly *when the eruption is scanty* the temperature extremely high and the patient in a state similar to shock When measles breaks out among populations from which it has been long absent, the disease may be extraordinarily severe and tends to attack individuals regardless of age Thus in the *Faroe Islands in 1846 six* thousand persons out of a population of 7 782 were attacked and it is estimated that about a quarter of the population died within three months The Territory of Hawaii experienced in 1936–1937 the most virulent epidemic of measles in its recorded history This *epidemic* began in November 1936 and lasted until December 1937 The incidence equalled that of the preceding twenty years and was accompanied by a high mortality Such epidemics have seldom been encountered in the continental United States In 1940 the case fatality rate of measles in the *United States* registration area was about 0.2 per cent Even the reported death rate may give an exaggerated picture of the dangers of the disease inasmuch as the actual incidence of measles has been estimated to be two to three times the number of cases reported

Prophylaxis—The public health measures employed for the control of communicable diseases such as reporting of cases placarding of homes and isolation of patients have been inadequate to prevent the spread of measles Infectivity begins with the onset of symptoms or shortly before and persists probably *until* the peak of the eruption is reached Communicability is thus probably greatest before the appearance of the rash It is to be emphasized that measles patients apparently will not spread measles after the rash has faded In most communities isolation of patients is required for four or five days after the appearance of the eruption or until the eruption has faded Exposed children who have been in intimate or direct contact with a patient should be kept under quarantine beginning eight or nine days after the first *known* contact and continuing until fifteen days after contact has ceased If serum is administered for the modification of the disease quarantine of the contact should be continued until eighteen days after the last exposure In a ward of susceptible children where the onset *and duration* of contact can be established it is safe to keep the ward open for one full week before the *isolation of the exposees* is necessary Although 95 per cent or more of the population sooner or later acquire measles unnecessary exposure should be avoided particularly of older infants and children of preschool age The importance of isolation of patients with measles is less perhaps *in the prevention* of the spread of the disease than in minimizing the incidence of secondary infection

No satisfactory means of *active immunization* against measles has been developed The studies of Shaffer Rake and Stokes must be considered as encouraging but successful *repetition of these trials* is needed Until the material for active immunization or for the production of the attenuated disease by a modified or attenuated virus shall have been further tested the prevention or modification of the disease by the use of human immune bodies remains the most effective *means of prophylaxis* With complications occurring less frequently and in the presence of a steadily declining death rate fewer indications exist for the use of serum in prevention or modification of measles Antibodies against measles are found in the blood of almost all patients who have recovered *from the disease* The antibodies are probably of highest titer in fresh convalescent serum but apparently persist in protective quantities throughout life possibly augmented by re-exposures Since no *small* laboratory animal is readily susceptible to measles an adequate means of titering the antibodies has not been devised In 1923 Debre described a test for the inhibition of the rash in measles by intracutaneous injection of serum Unlike the Schultz Charlton blanching test in scarlet fever the *measles serum had to be* introduced before the rash developed in the area of injection Fresh convalescent serum even in 2 per cent solution may produce the Debré phenomenon whereas adult immune serum *and placental* extracts are seldom effective in solutions weaker than 5 per cent

Convalescent serum adult immune serum and *immune globulin* derived from the human placenta may all be effective in the prevention or modification of measles Three to 6 cc of blood serum of convalescent patients (blood taken a week or more after the disappearance of the measles eruption) injected subcutaneously or intramuscularly into the exposed child within four days after exposure usually gives complete protection This immunity however is passive in character lasts but a few weeks and usually suffices to cover only the one exposure If adult immune serum is used 15 to 20 cc are required The effective dose of immune globulin varies from 2 to 4 cc depending upon the preparation employed If antibody

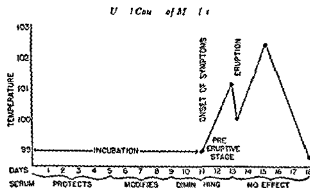

Fig 3—The effect of convalescent serum adult immune serum or immune globulin (placental extract) on the usual course of measles

is given as late as the sixth or eighth day after exposure protection usually does not ensue but the disease may be ameliorated to a modified or attenuated type The incubation period may be prolonged to as much as seventeen to eighteen days The severity of the disease is reduced and complications are less frequent yet the attenuated attack usually results in a permanent immunity The treatment of measles during the pre eruptive stage by convalescent serum in dosages of 40–50 cc by intravenous injection has been advocated Amelioration of the severity of the symptoms can often be obtained up to the appearance of the eruption but later use of the serum is without effect Local reactions are frequently encountered following the use of placental extract but seldom following the injection of convalescent serum or adult immune serum

Treatment —While chemotherapy has not developed a drug effective against measles further reduction of an already low death rate has been achieved through the use of sulfonamide compounds in the treatment of the bacterial complications

Rest in bed adequate food and fluids care of the bowels protection of the eyes, emollient applications to the nose and sedatives to counteract cough are usually the only therapy required in uncomplicated measles The room occupied by a measles patient should be well ventilated and kept warm Cold air seems to irritate further the mucous membranes affected by the disease Should symptoms of tracheitis or bronchitis be distressing higher temperature and increased humidity may add to the comfort of the patient In severe cases of laryngitis croup tents with steam inhalations may give relief The eyes usually need no protection other than that obtained by avoidance of bright light The short duration of the disease renders the problem of nourishment of minor importance

Antipyretic treatment may be necessary when the temperature becomes high but usually only if the pyrexia is accompanied by nervous symptoms such as restlessness stupor delirium or convulsions Coal tar antipyretics such as phenacetin or antipyrene are usually effective but warm alcohol or tepid water sponges are preferable Acetylsalicylic acid in doses of 5 to 10 grains may achieve the same results The fall in temperature is usually accompanied by a marked diminution of systemic symptoms Convulsions which sometimes occur at the onset of a febrile illness in children may be observed at the onset of measles Usually treatment for the pyrexia results in the cessation of convulsions Occasionally phenobarbital or paraldehyde may be necessary to control the attack

Sulfonamide compounds have been found to be effective in the treatment of the bacterial complications particularly those due to the streptococcus or pneumococcus Sulfathiazole or sulfadiazine seem at present the preparations of choice since they have a wide bacterial coverage and are well borne by infants and children The dosage should be approximately 1 0 grain (0 065 Gm) per pound of body weight per day for a child up to five or seven years of age Since the

greatest dangers of measles are due to the development of complications sulfonamides may be given prophylactically to a child during the attack of measles if he has been acutely or chronically ill preceding the onset of the disease With the advent of chemo therapy, most of the symptomatic procedures used in the treatment of postmeasles bronchopneumonia have become of secondary importance However occasionally the bronchopneumonia is of nonbacterial origin possibly of the so called virus or atypical type Under such circumstances only symptomatic treatment is available In these cases the temperature is usually not high but the respirations are rapid and the physical signs diffuse and accompanied by considerable cyanosis The position of the patient should be changed frequently to prevent pulmonary congestion Sedatives should be used sparingly so that the cough will be relieved but not inhibited as coughing or deep breathing and crying apparently minimize occlusion of the smaller bronchi An oxygen tent may become necessary in some cases

Otitis media in measles may give rise to serious complications Frequent changes of the patient s position in bed are thought to help prevent the incidence of otitis *Paracentesis* of the tympanic membrane is not recommended except in the presence of persistent pain together with bulging of the ear drum Relief of pain is prompt with paracentesis although pus may not be discharged until several hours later Many of the cases of otitis media in infancy and childhood clear up without the development of suppuration especially if sulfonamide drugs are used in therapy Dry wipes of the discharging ear are usually all that is necessary Wicks in the ear are not desirable nor are irrigations necessary unless the purulent discharge becomes thick and occludes the canal

There is no satisfactory treatment for *measles encephalitis* Patients may be kept quiet by sedation with phenobarbital paraldehyde or in very severe convulsive cases by avertin

In *convalescence* from measles the child s activity should be restricted until his strength has returned Most important in the treatment of measles is the attempt to prevent secondary respiratory involvement Attendants upon patients with measles should wear an outer garment which can be removed before contact is established with the rest of the family The hands should be scrubbed thoroughly on leaving the room occupied by the patient Because of the susceptibility of measles patients to bacterial respiratory infection masking of the attending personnel is indicated The dishes and linen of the patient should be boiled after each use The heavier bedding such as blankets and mattress and the whole room should be aired thoroughly when the disease has subsided

RUBELLA

(*German Measles Rotheln*)

Definition —Rubella is an acute specific epidemic and highly contagious disease similar to but quite distinct from measles and scarlet fever It is characterized by a long incubation period short invasive stage benign course and almost complete freedom from complications

Etiology—Although the *specific agent* has not been definitely isolated it is probably a filtrable virus which is present in the buccal and nasal secretions The disease is transmitted chiefly if not entirely by direct contact The possibility of infection through fomites or a third person has not been determined The infectivity is less than that of measles and of short duration Like measles rubella is infectious for only a day or two before the eruption appears

Rubella is prevalent during the first half of the year The *incidence* begins to rise during January becomes maximal in May and June, and then falls abruptly The characteristic local outbreaks occur among aggregations of unprotected individuals Although children between the ages of three and twelve years are most susceptible young adults who have not had the disease during childhood are frequently attacked Children who had measles develop rubella more often than children who had not Infants under six months of age have a certain degree of immunity One attack almost invariably protects against others but not against measles or scarlet fever Every three or four years a more or less pronounced epidemic occurs and occasionally an outbreak of severe rubella resembling measles is reported

Symptoms—The period of *incubation* varies from ten to twenty two days but is usually seventeen or eighteen days A short period of pharyngeal catarrh usually precedes the rash by about twenty four hours Rarely a longer prodromal period of ill defined discomfort occurs before the eruption appears The characteristic adenitis of the mastoid occipital and cervical glands can in the majority of cases be detected a day or two before the appearance of the rash

The *rash* is papular and morbilliform in the beginning but frequently becomes scarlatiniform in the second stage It appears as discrete round or oval spots first on the face or neck around the mouth or behind the ears and occasionally on the scalp Sometimes the wrists chest shoulders or even the legs are affected first The rash which spreads rapidly downward may cover the entire body in the course of a day In most cases it fades as rapidly as it develops so that the face is almost clear by the time the lower extremities are involved The papules which are smaller than those of measles are pink in color and tend to cluster in small groups The rash may be scarlatiniform on the second day This is most marked on the trunk, especially on the back The rash rarely persists more than seventy two hours and hardly stains the skin contrasting in this respect with measles It may be followed by a three day desquamation

The mucous membrane of the *mouth* is not inflamed and Koplik's spots never occur Fine vesiculation and congestion of the soft palate are often seen The tonsils may be slightly swollen and reddened and there may be some pharyngeal catarrh The *conjunctivae* are pink and the eyes slightly suffused Photophobia is rare The *temperature* usually rises as the rash appears but rarely exceeds 101° F The increase seldom lasts longer than two or three days Often there is no fever at all

The *adenitis* which is very distinctive involves the mastoids occipital posterior cervical and frequently the axillary and inguinal glands These usually become enlarged to the size of small peas and are firm discrete and tender They resolve rapidly without suppuration when the rash subsides The blood undergoes no characteristic changes

Convalescence is rapid A slight furfuraceous desquamation may occur

Complications and sequelae are rare and trivial although otitis arthritis nephritis endocarditis and encephalitis or meningoencephalitis have been reported occurring chiefly in severe epidemics Encephalitis occurs less frequently than after measles the patients appearing dangerously ill but usually recovering quickly and completely Mild recurrent sore throat slight laryngitis slight bronchial catarrh mild rheumatic pains or transient albuminuria are those more commonly observed

Diagnosis—Rubella is confused chiefly with the mild forms of measles and scarlet fever especially when it is severe *Measles* can be differentiated by the shorter incubation period of fourteen days by the marked catarrhal symptoms the presence of Koplik s spots a more severe constitutional reaction and the rash which is darker and more persistent and stains the skin *Scarlet fever* has an even shorter incubation period

(about seven days) and is characterized by initial vomiting headache, and high fever, and the absence of rash upon the face Rashes caused by toxins and drugs are usually polymorphic and irregularly distributed They are not accompanied by the glandular enlargement characteristic of rubella *Erythema scarlatiniforme* bears a greater resemblance to scarlet fever than to rubella it avoids the face does not cause enlargement of the mastoid or occipital glands and tends to recur *Pityriasis rosea* which is perhaps an infective fever may be distinguished by the so called Herald patch which precedes the general eruption, as well as by the usual primary localization on the upper part of the trunk In this disease the patches are scaly often macular and ringed The papules which are decidedly larger and more persistent than those of rubella desquamate characteristically from the center toward the margin *Secondary syphilids* bear a superficial resemblance to the rash of rubella but may be easily differentiated

Prognosis.—Recovery is the rule Although rubella is known to recur second attacks are not common Relapses occur very rarely

Treatment.—*Prophylactic*.—Exposed individuals should be isolated from the tenth to the twenty first day after exposure to the infection A careful watch should be kept for tenderness and swelling of the mastoid and occipital glands Pooled human serum or plasma is effective in the control of epidemics and if used more generally would reduce markedly the incidence of this disease

Therapeutic.—The patient should be isolated and kept in bed until all symptoms have subsided If no complications develop quarantine may stop after seven days although the Association of Medical Officers of Schools advises that it continue for ten days

HERPES SIMPLEX

(Herpes Febrilis Symptomatic Herpes Fever Blisters Cold Sores)

Definition.—Herpes simplex is an acute infectious disease of man characterized by groups of superficial watery blisters in the skin or mucous membranes The malady is transmissible to lower animals particularly rabbits

Etiology.—Löwenstein and Grüter showed that an infectious agent is the cause of herpes simplex Since the reports of their work ample evidence has been adduced to justify the classification of the agent, possessing a diameter of 100 to 150 millimicrons with the filtrable viruses Doerr and Vöchting and many others have shown that this virus is also capable of attacking the central nervous system of experimental animals

Incidence.—Some herpetic eruptions appear without apparent association with other pathologic conditions others are secondary to, or are associated with such diseases as malaria pneumonia and cerebrospinal meningitis still others *e g* menstrual herpes recur at the same spot at regular intervals Injections of foreign proteins *e g* vaccines or fever therapy frequently precipitate an attack of herpes

Symptoms.—The lesions may occur anywhere in the skin of the body including the genitalia in the conjunctiva and in the cornea At times particularly in the skin of the face the distribution is similar to that of zoster lesions and in these instances the virus can be recovered from the nerves or ganglia supplying the affected area The lesions first appear as painful swellings which quickly develop into watery blisters surrounded by areas of erythema The symptoms caused by herpetic infection except the local lesions are not clearly defined because

the malady usually accompanies other diseases Some observers however hold that an uncomplicated herpetic infection may produce chills fever, headache malaise, and anorexia which disappear in two or three days

Pathology —Hyperplasia of epithelial cells which then are destroyed to form vesicles and the development of inflammation in the corium are the changes observed in affected tissues Nuclear inclusions characteristic of many virus diseases are seen in infected cells

Prognosis —Unless a secondary infection occurs recovery is the rule but one attack does not protect against subsequent ones

Treatment —After the appearance of lesions treatment should be symptomatic Tanning of the skin which is subject to recurrent attacks of herpes seems to lessen their number and severity

HERPES ZOSTER

(Shingles Zona Zoster)

Definition —An acute specific infectious disease characterized by inflammation of one or more dorsal root ganglia or the extramedullary ganglia of the cranial nerves and accompanied by an eruption of irregularly outlined groups of vesicles distributed along the course of the corresponding peripheral sensory nerve

History —This disease long known as a clinical entity and named by the Greeks zona was first shown to be related to inflammation of the corresponding dorsal root ganglion by Barensprung in 1863 The classical paper of Head and Campbell (1900) gave a firm foundation of its neuropathology and Lipschutz in 1921 defined the specific features of the cutaneous vesicular lesion Bokay s observations (1909) indicated its possible etiologic relation to varicella those of Teague and Goodpasture (1921) pointed out its similarity to certain lesions of herpes simplex and Kundratitz (1925) first reported successful experimental inoculations into human subjects Others have failed to transmit the infection experimentally

Etiology —Evidence of the infectious nature of herpes zoster is afforded by such clinical manifestations as variable systemic disturbances fever and subsequent immunity by its epidemiologic features of occasional epidemic outbreaks and seasonal incidence by the specific cytologic characteristics of its cutaneous lesions and by reported successes in experimental transmission to human subjects

More specifically evidence indicates also that the disease is due to a filtrable virus although the virus has neither been definitely demonstrated by experimental transmission in series nor consequently filtered The most direct indications that the active agent is a virus are the presence of acidophilic *intranuclear inclusions in cells of the* cutaneous eruption its contagiousness reported successes in transmission and the manifestations of active immunity following an attack

Morbid Anatomy —The classical studies of Head and Campbell demonstrated that the basic lesion of the manifest disease is located in one or more dorsal root ganglia or the gasserian ganglion corresponding to the sensory nerve distribution to the areas of eruption They showed that the changes in the dorsal root ganglion are situated in its dorsal aspect *i e* in that portion opposed to the anterior root and in the acute stage consist of severe inflammation with exudation of small round deeply staining cells extravasation of blood destruction of ganglion cells and fibers and inflammation of the sheath of the ganglion

These changes are followed by acute de

generation in the peripheral nerve in the posterior nerve root and in corresponding fibers of the spinal cord The inflammatory focus in the ganglion on healing becomes transformed into a fibrous scar depending in its size and density upon the extent of the original inflammation but usually occupying from one sixth to one half of the ganglion All the ganglion cells and nerve fibers within the scar are destroyed The sheath over the scar is thickened If the inflammation is mild the ganglion may be left apparently normal In rare cases paralysis of local muscles indicates involvement of the fibers or neurons of the anterior horns

The cutaneous vesicle rising from an erythematous base is situated in the epithelial layer and its floor is formed of naked papillae There is marked inflammation of the corium at the base with congestion edema and infiltration by mononuclear cells The vesicle may be divided into compartments by septa which are remains of incompletely separated epithelial layers retaining their attachments The yellowish fluid within the vesicle is either clear or slightly cloudy from the presence of desquamated epithelium and inflammatory mononuclear cells

Acidophilic intranuclear inclusions especially numerous in earlier stages are found in epithelial cells about the vesicle They occur also in the connective tissue cells in the adjacent corium These inclusions first described by Lipschutz constitute the specific element in the lesion and indicate the activity of a virus No similar inclusions have been described in the cells of the affected ganglion and if present they would be demonstrable probably only in the earliest stages of the lesion

Nothing is definitely known about the portal of entry of the suspected virus although the rather frequent occurrence of cases of so called symptomatic herpes zoster secondary to ome irritating or injurious lesion about the ganglia such as tuberculosis syphilis or tumor indicates that it may be commonly present in the environment or perhaps often latent in the human tissues

Head and Campbell showed in their analysis of over 400 cases that the dorsal ganglia most frequently affected are those that receive afferent fibers from the viscera through the white ramus of the sympathetic branches This fact in view of the present hypothesis of spread of certain neurotropic viruses along axons at least suggests the possibility of initial peripheral foci of infection with secondary localization within a ganglion followed by injury and necrosis of its cells accompanied by hemorrhage and inflammation Virus liberated from infected neurons presumably extends centrifugally to localize in cutaneous epithelial cells in contact with the corresponding peripheral terminations of nervous filaments As a consequence of degeneration and necrosis of these cells the vesicle with its attendant inflammatory phenomena appears The probability of such a course of events is suggested by the experiments of Teague and Goodpasture with the virus of herpes simplex which if inoculated into the tarred skin of rabbits or guinea pigs will cause a specific ganglionitis and zosteriform eruption quite similar to that of herpes zoster in man

Signs and Symptoms—In cases of so-called essential or idiopathic herpes zoster a typical attack arises without any obvious peripheral or central cause There is a prodromal period usually of three or four days duration during which the patient feels ill the temperature is elevated and there is more or less pain At this time a definite diagnosis cannot be made but suddenly the erythematous and vesicular eruption appears with its characteristic distribution along the course of a nerve usually of the trunk occasionally in a trigeminal area There is often an increase in the number of cells in the spinal fluid

The febrile period lasts usually from three to five days and with its subsidence drying and healing of the cutaneous lesions take place Secondary infection may delay healing and increase the tendency to scarring Neuralgic pains may persist especially in elderly people and rarely there is some local residual paralysis

Herpes zoster of the face is not uncommon and is often severe It involves the first branch of the sensory division of the trigeminal nerve and may lead to severe corneal ulceration which requires special care The other cranial nerves are rarely affected

Diagnosis—Because of the characteristic nervous distribution of the cutaneous vesicular eruption the diagnosis is usually not

difficult after the rash appears In children and rarely in adults the local eruption may be followed by the appearance of more or less generalized vesicles unrelated apparently to cutaneous innervation In such cases of a generalized vesicular exanthem there may be a question, especially in children, whether or not the disease is in reality varicella Indeed there is considerable clinical and epidemiologic evidence that the two viruses, that is those of herpes zoster and of chickenpox are the same or very closely related etiologic agents The histopathology of the cutaneous lesions offers no distinction between the two for as was shown by Tyzzer in 1906, acidophilic intranuclear inclusions occur in the epithelial cells about the vesicles and in the corium of cutaneous lesions of varicella, and these, as well as other elements of the inflamed skin are similar to those of herpes zoster

Occasionally the virus of herpes simplex causes a vesicular eruption along the course of a cutaneous nerve usually quite limited in extent and it may involve the supra orbital branch of the ophthalmic nerve This may simulate a mild herpes zoster very closely The presence of the virus of herpes simplex can be determined, however by inoculating vesicular contents into the scarified cornea of a rabbit Herpes simplex virus is very infectious for the rabbit and if present in the test a profound herpetic keratitis not infrequently followed by encephalitis will ensue The viruses of herpes zoster and of varicella on the other hand have never been proved to be successfully inoculable into other than the human host

Treatment —There is no specific treatment for the infection Alleviation of irritation and pain and prevention or care of secondary infection are the indications for therapy in the essential variety In some cases of the symptomatic type which may recur treatment of the associated disease or local lesion may be helpful as for example of cerebrospinal syphilis which is not infrequently accompanied by herpes zoster

According to Kraus the pain in the acute stages should be relieved by codeine in ½-grain doses given every four hours The skin lesions may be covered with collodion If ruptured an ointment of 1 per cent cocaine in lanolin is advisable Recently deep x ray therapy has become a popular method of treating herpes zoster The dosage is 200 to 250 R U a day for five or six days directly over the dorsal ganglia involved The best results are obtained when roentgen therapy is used early in the course of the disease, that is during the first two to three days Subcutaneous injections of pitressin have been advocated by some but there is no rationale for such a treatment and the results are disappointing

The post herpetic neuralgia may be very refractory to treatment Aspirin pyramidon and codeine may be used for the relief of pain Cobra venom has also been tried with some success Severe intractable root pain occasionally has to be treated by posterior root section

VARICELLA

(Chickenpox)

Varicella is a mild communicable disease of childhood characterized by fever and a vesicular eruption with erythema around the vesicles involving the skin over the entire body and the mucous membranes of the mouth and throat

Etiology —The causative agent of varicella has not been identified but probably like other pox infections it is due to a virus A striking characteristic of varicella in which it resembles measles is the highly communicable nature of the virus which appears to spread chiefly by the air borne route

although direct contact and droplet "hits" from sneezing coughing or speaking at times must play an important role The virus apparently enters through the respiratory tract and is spread by the same route during the early catarrhal stages of the disease when mild inflammatory reactions of the mucous membranes of the nasopharynx are more evident Spread of the disease also occurs from the vesicles on the skin during the early stages of the eruption but probably no spread of the virus occurs after the appearance of crusts The virus has not been grown successfully on the chick embryo or its membranes as yet and other animals than man do not appear to be susceptible A close relationship may exist between the virus of varicella and that of herpes zoster in that epidemics of varicella are associated with attacks of herpes zoster and herpes zoster has been said to incite epidemics of varicella or to be associated with their inception Although there may be a certain degree of cross immunity existing between varicella and herpes zoster accurate determination of their relationship cannot be made until satisfactory methods for identification of the virus of varicella are developed

Immunity is usually permanent following a single attack Transplacental passive immunity may be present in newborn infants although cases have been recorded in infants within the first two weeks of life The rarity of exposure of newborn infants to varicella has delayed conclusive evidence on this question

Incubation —The incubation period usually is fourteen to sixteen days but in many instances the first symptoms and signs occur as late as twenty-one days from the time of exposure

Symptoms and Signs —Prodromal symptoms may be severe particularly in adults but in childhood they are apt to be mild or absent with nasopharyngitis mild fever headache malaise and anorexia Within twenty four to forty eight hours crops of papules and later of vesicles begin to appear on the face and trunk particularly about the shoulders and usually a few appear on the buccal mucosa or pharynx The large majority of lesions are vesicular The vesicles are slightly elevated with a surrounding circular erythema or areola and it is difficult to mistake them for any other lesion except possibly those of variola In variola however in addition to the severity of the symptoms and the more extensive character of the rash the vesicles appear almost simultaneously and are usually larger with a greater tendency to umbilication

In varicella the appearance of fresh crops of vesicles in the same area of skin over a period of twenty four to seventy two hours is characteristic and for this reason in contrast to variola the lesions are usually seen in various stages of development some as small translucent vesicles some with slight umbilication as the vesicles dry from the center, and some with dry firmly attached crusts Also in variola the severe symptoms precede the eruption while in varicella the symptoms accompany the eruption unless the disease is unusually severe Severe irritation and itching usually accompany vesiculation in varicella and for this reason in younger children the larger lesions are rarely permitted to heal "by first intention" unless care is taken to prevent scratching and to relieve the severe itching Excoriated areas and larger crusts are the inevitable result

On the buccal mucosa or the pharynx the vesicles early become small ulcer craters with a surrounding erythema and resemble closely the type of ulcer so frequently seen in herpetic stomatitis Two particularly annoying points of attack are the larynx and the conjunctivae At times vesicles in these structures may be dangerous because of complicating bacterial infections The genitalia also must be examined daily since lesions on these areas are often scratched and secondarily infected Another area frequently overlooked is the scalp where the matting of hair over scratched and crusted lesions results in severe secondary bacterial infections with enlarged and tender occipital and posterior cervical lymph nodes

In the mildest cases only ten to twenty lesions may appear on the skin and there may be no fever or only a transient fever of a few hours in the more severe cases the discrete vesicles will dot the entire body surface and the temperature rises to 103° or 104° F for several days at the time of the appearance of the rash The disease in adults may at times be dangerously severe

before and during the appearance of the eruption Rarely, *necrosis occurs around* the vesicles resulting, if widespread in lesions which have been termed varicella gangrenosa

Complications —The most severe complications may occur in those children who are subject to eczema or staphylococcic infections of the skin In such children the vesicles rapidly fill with pus and are usually ruptured by scratching, with a resultant spread of infection and ulceration Such ulceration and crusting are typical of impetigo contagiosa and many cases of varicella observed first in the late stages would be diagnosed as impetigo were a proper history not available Following the usual case of severe varicella, a few small scars or pox marks remain about the face or shoulders even though scratching has been avoided but in the secondarily infected case with pus and crusting the pox marks may be large and disfiguring Hemolytic streptococci resulting in severe cellulitis and erysipelas have been less common secondary invaders but, until the advent of the sulfonamide drugs, they were the complicating organisms most feared A small percentage of cases of acute glomerular nephritis are the result of skin infections, and varicella with its complications plays an important role in this group of causative factors Pneumonia from laryngeal ulceration abscesses of lymph glands draining secondarily infected areas and serious eye infections are other less common complications to be avoided by proper preventive measures

A rather infrequent but important complication due probably to the activity of the virus only is encephalitis which is similar to that caused by measles and by other communicable diseases It occurs in the more severe cases of varicella usually toward the end of the febrile period but may at times appear one to three weeks following the attack of the disease It is rarely fatal and complete recovery usually occurs

Diagnosis —The appearance of vesicles on the skin each surrounded by a ring of *erythema and* accompanied by a fever however slight is the *sine qua non* of varicella If the disease is seen in this stage of vesiculation and when the crops of eruption in the various stages of translucent vesicles vesi

which may reach the height of 106° or 107° F In children convulsions and vomiting or drowsiness quickly followed by coma may occur The patient is usually prostrated the face is flushed the pulse is usually full and bounding and marked restlessness which at times amounts to delirium supervenes

Transient rashes resembling scarlet fever or measles may occur during the *prodromal stages* of the disease while the temperature is approaching or when it has reached its highest point Such rashes occur only during the first two days and are found usually over the lower abdomen and the inner aspects of the thighs The position of the rash and its lack of elevation serve to distinguish it from measles or scarlet fever At times such a rash initiates the more severe types of smallpox

On the third or fourth day, *raised macules* begin to appear over the face The earlier these macules appear, the more likely is the rash to become confluent The macules rapidly develop into *papules* and with this development there is associated an immediate diminution in the severity of symptoms and the fever the patient becoming considerably more comfortable The fever and symptoms may increase again later with the multiplication of staphylococci or streptococci in the pustules with their attendant complications The single crop of papules are firm and shotty 2 to 4 mm in diameter with an appearance unlike any other exanthematous disease Widespread tuberculids all of the same size and symmetrically distributed could have the same appearance With the increasing size and tenderness of the papules *multilocular vesicles* begin to form over the papules on about the sixth day characteristically umbilicated due to a dry and depressed center Some vesicles are superficial while others are deeper and not so readily recognized By approximately the eighth day the vesicle becomes full of cloudy fluid and the typical *pustular rash* is in full bloom The pustular nature of the lesion apparently is not dependent upon the presence of secondarily invading bacteria although they are usually present and greatly increase the danger of complications The pustules are slightly larger than the papules with somewhat greater elevation and have a very characteristic greenish or grayish yellow color A small red areola forms about each lesion at the time of vesiculation a phenomenon which occurs synchronously with the development of an allergic response of the skin to variolous material

Although the lesions may vary slightly in size they proceed through each stage of development at the same time—do not appear in crops as is characteristic of varicella with which otherwise mild smallpox might be readily confused While all of the lesions appear at approximately the same time a small percentage of them do not progress through all of the characteristic steps but remain at times only as papules or with very slight evidence of vesiculation In such lesions involution occurs frequently in the earlier stage of the disease

The rash usually appears on the face and about the wrists only slightly in advance of its appearance on the rest of the body and then rather rapidly involves the rest of the forearms upper arms and thorax The abdomen and legs are often only slightly involved but in severe cases this may not be true Such severe cases in which the rash is widespread and where the lesions are so closely studded over the skin that they coalesce are termed *confluent* smallpox; whereas in the absence of coalescence the term *discrete* smallpox may be used

Frequently these two forms confluent and discrete occur in the same patient the confluent lesions appearing on the face and about the wrists while the discrete lesions appear on the thorax abdomen and legs In certain confluent lesions the area involved has almost the appearance of a large abscess On the face these lesions can be particularly distressing often producing extreme discomfort edema may close the eyelids and involve the tissues of the neck as well Edema of the hands and feet often occurs in children At the height of the pustulation lesions frequently occur in areas which must be watched closely for secondary infection the mouth and nasopharynx the prepuce, the labia and the vagina Lesions on the palms and plantar surfaces are not apt to develop into vesicles and pustules but nevertheless form crusts Marked pitting of the face or arms occurs as a rule only in the confluent form of the disease

With the appearance of pustules in the more severe cases, the temperature which has fallen with the earlier appearance of the papules again begins to rise and subsides only when satisfactory crusting has occurred Staphylococcic and streptococcic invasions of the pustules apparently are chiefly responsible for the secondary febrile reaction The pustules and crusts itch severely and scratching must be prevented Desquamation may begin at the twelfth to the fourteenth day and unlike the branny desquamation of measles and scarlet fever the desquamating crusts are thick and brownish yellow in appearance A dark blue dis-

Fig 5—Smallpox in an unvaccinated child showing distribution of eruption

Fig 6—Same patient as Fig 5 showing eruption on back and palms

(Reprinted from the article of Dr Murray Cowie in the 5th edition of Cecil's Textbook of Medicine)

coloration of the skin occurs in the area from which the crust has separated but this gradually and completely disappears

Blood—There is usually a leukopenia together with a relative mononucleosis in the earlier stages of the disease but later a leukocytosis occurs particularly during the pustular stage and when secondary complications occur Anemia usually occurs together with enlargement of both the spleen and the liver In the two hemorrhagic types of smallpox previously mentioned considerable depression of the bone marrow and the liver may occur resulting apparently in alterations in the platelets fibrinogen and prothrombin The exact origin of such hemorrhagic phenomena however is not entirely clear

Varioloid—This term is usually applied to smallpox modified by a vaccination which has 'taken' successfully within approximately five years The lesions are of the discrete type the prodromal symptoms are rarely severe there is no secondary rise of fever and the lesions frequently undergo involution with a markedly shortened course

Abortive Types—Occasionally in recently vaccinated individuals early involution of the eruption occurs even before vesicles are well established and in rare instances the eruption never develops a condition which is known as *variola sine eruptione*

Complications—The common complications of smallpox may be considered as largely due to the secondary invasions of staphylococci and streptococci Abscesses septicemia nephritis erysipelas laryngitis and the various lower respiratory infections can usually be traced to these organisms together with, at times the pneumococcus Corneal ulcers and pustules of the eyelids are not uncommon Rarer though still important complications are diarrhea and otitis media in children while in adults the rare complications are hemiplegia enceph

alitis polyneuritis decubitus ulcers and gangrene

Diagnosis —Difficulties in diagnosis arise chiefly from the following conditions

Varioloid with the involution of many of the lesions can be confused at times with varicella In such cases one must depend upon the appearance of varicella in crops of lesions in all stages of development and also upon the difference in distribution of varicella which is more plentiful on the trunk

The *severe hemorrhagic forms* can be confused with septicemia or severe meningococcal infection Blood cultures should establish the diagnosis

The *initial rash* which occurs in severe forms may be confused with measles or scarlet fever The short duration of the early evanescent rash of smallpox and the other accompanying symptoms should assist in differentiation

Pustular syphilids are at times extremely difficult to differentiate from smallpox In certain instances one can depend only upon the history and the Wassermann reaction for differentiation

The injection intradermally of heat killed vaccine virus may be used also as a diagnostic test for smallpox after the vesicles have appeared or the contents of the vesicles may be used in a similar manner If positive for smallpox a local reaction occurs at the site of injection within a few hours and reaches its maximum within approximately twenty four hours If the patient has been vaccinated previously this test is not significant A similar test has utilized rabbits sensitized to cowpox vaccine and the vesicular contents The vesicular contents have also been used as antigen in a complement fixation test with serum from sensitized rabbits

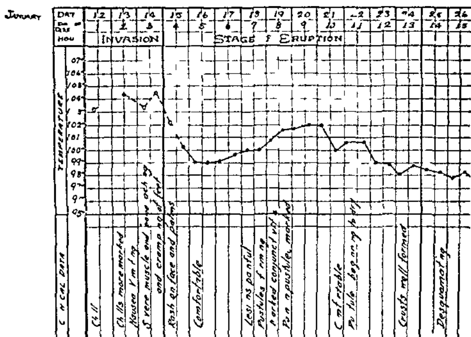

Fig 7—Typical temperature curve from a case of smallpox illustrating the secondary rise (Reprinted from Dr Murray Cowie s article in the 5th edition of Cecil s Textbook of Medicine)

The use of rabbits limits the availability of the latter tests but the intradermal injection of heat killed vaccine virus may be of assistance in difficult diagnostic problems

Prognosis —The prognosis in smallpox depends largely upon the severity of the particular case In the epidemics of recent years the mortality has been distinctly lower than in the prevaccination era The cases accompanied by high fever are more likely to be fatal Complications particularly those in the respiratory tract add to the seriousness of the prognosis

Prophylaxis —The problem of vaccination is considered properly under the chap

ter on Vaccinia Emphasis must be placed upon the fact that vaccination even during the incubation period of the disease may prevent its development Strict quarantine is essential

The disease at times is air borne as well as being transmitted by contact or by direct droplet "hits" from the patient's nasopharyngeal secretions and means of sterilization of the air, if practicable must be considered as well as the prevention of close contacts and of spread by fomites

Treatment —The principal consideration in the treatment of smallpox is the prevention of secondary infection of the vesicles and pustules The secondary elevation of temperature which usually follows the appearance of the vesicles and pustules is probably dependent upon the bacterial invasion of the lesions, and particularly by staphylococci and streptococci Treatment therefore should be aimed essentially as in varicella, toward the prevention of itching and the cleansing of fingers the skin and garments or clothing which may come in contact with the lesions Also scrupulous care must be taken by those caring for the patient The advent of the sulfonamide drugs and recently also antibiotic preparations such as penicillin or penatin should assist greatly in the local treatment of the lesions of smallpox Swabbing the lesions in wet dressings of potassium permanganate 1 4000 may prevent serious infection A 20 per cent sulfonamide suspension in water or similar suspensions appear preferable to sulfonamide ointments due to crusting but it is important that crusts should not be removed too quickly in view of the possible resultant scarring Bathing the lesions gently with hot water or antipruritic lotions should be done to alleviate the itching although here also the sulfonamide preparations are of assistance

Dehydration is a frequent severe complication of smallpox and should be avoided by rectal intravenous or hypodermic fluids particularly glucose if vomiting occurs The possible benefit of convalescent serum has not as yet been determined The isolation period should be at least fourteen days and longer if the lesions remain in an active stage

VACCINIA

Vaccination or active immunization against smallpox by means of the virus of cowpox is the first procedure of this type known to medicine and its discovery and development by Jenner long before bacteria or viruses had been identified is one of the most dramatic events of medical history The antigenic serologic or possible morphologic relationships between the viruses of cowpox and smallpox are not understood as yet although in view of the proved immunity produced by vaccination with the cowpox virus against smallpox these relationships must be very close

The virus of cowpox has been ordinarily preserved by glycerination of lymph from inoculated calves More recently it has been grown in tissue cultures by the methods of Rivers and Goodpasture which have almost entirely eliminated bacterial contamination These latter preparations can be used intradermally and produce a much milder reaction with a closed lesion Although the protection afforded against smallpox is probably as solid as that produced by the more usual material sufficient experience with its value in the face of an epidemic of smallpox

has not been obtained as yet to warrant its widespread use

Proper Age for Vaccination —In view of the fact that severe reactions and particularly the complication of encephalomyelitis are less apt to occur when vaccination is performed during the first year, it is best to vaccinate an infant at about the fourth to the sixth month The choice of months however should vary according to a number of factors It is essential that no fixed or invariable order of immunization procedures be followed in infants since epidemics of communicable diseases respiratory infections the convenience of the family and the physician the weather and other factors should all be considered in such procedures It is wise to avoid hot weather because of the possibility of a marked febrile reaction and to avoid vaccination within a certain period following illness and until the latter half of the first year in premature infants or those who have suffered from nutritional difficulties The presence of such cutaneous conditions as eczema impetigo and others should cause postponement of vaccination until the skin is normal but in chronic eczema or in other cutaneous conditions which are not readily curable tissue culture virus injected by the intradermal method can often be used successfully with less danger of bacterial contamination

Choice of Site for Vaccination —It is common practice for girls to be vaccinated on the outer skin of the thigh or on the skin covering the peroneal muscles in the middle of the leg whereas boys are more frequently vaccinated near the insertion of the deltoid muscle on the arm The rubbing of the soiled diaper over the involved area presents certain disadvantages for the thigh area in infants although with sufficient care secondary infection usually can be avoided here also The area of choice therefore is the *outer skin on the middle of the arm or leg* Certain physicians have preferred the inner aspect of the arm in the belief that this area is more fully protected against severe trauma However this variable advantage is more than offset by the greater friction from the clothing and the moderate increase in moisture from perspiration which may occur in this area

Method of Vaccination —In the development of technics for vaccination over many years the objective has been to produce a lesion which results in as inconspicuous a scar as possible and yet which still produces an optimal degree of immunity Although serologic means of determining such immunity are not now available experience in the presence of epidemics of smallpox and with the results of revaccinations has indicated that the take from the recent methods of vaccination resulting in a small scar is as highly protective as the take with the large scar resulting from the older methods of vaccination Unfortunately, many physicians still believe that scarification or drilling of a large area of skin and the resultant disfiguring lesion are essential for a solid and more lasting immunity Even were this true the danger of secondary infections from the larger lesions and the added discomfort and fever would not justify such a procedure

The methods recommended at present are of three types (1) single scratch or incision method (2) drill method (3) multiple pressure method In these methods the objective is to permit the virus to enter the skin in as small an area as possible without sufficient trauma to draw blood The skin of the selected site should be cleansed thoroughly with sterile cotton and ethyl alcohol acetone or ether care being taken to avoid abrasions which might result in multiple takes The site should also be permitted to dry thoroughly after cleansing in order to avoid inactivation of the virus

(1) *Scratch or Incision Method* —A single scratch ⅛ to ¼ inch in length should be made in the skin with a sterile needle or point drawn through the drop of lymph More than one scratch may be made if the first appears to be insufficient but cross scratches should never be used The needle or point should then be placed horizontal with the skin and rubbed gently over the scratched area following which the drop of lymph should be rubbed off lightly with dry sterile cotton

(2) *Drill Method* —Multiple pricks are made through the drop of lymph with the needle held vertical to the skin surface The number of pricks should be limited to five or six and the lymph may then be wiped off with dry sterile cotton

(3) *Multiple Pressure Method*.—The needle or point is held at an angle of approximately 45 degrees with the skin surface and is moved up and down rapidly with pressure on the skin sufficient to puncture it lightly *six to ten times*. *Erythema but no blood or serum should be noted* following the procedure and the lymph may be wiped away immediately with sterile cotton, as in the other methods.

In all of these methods no dressing should be used, but scrubbing the area with soap and water should probably be avoided for *the following twenty four hours*.

Types of Reaction.—In general it may be said that the longer the incubation period the greater is the susceptibility of the vaccinated individual and the more severe is the reaction. The small sized reaction which occurs within the first twenty four or forty eight hours and disappears rather rapidly *denotes a high type of immunity*, whereas the usual "take" with the large reaction, which begins to develop typical signs after five or six days and reaches its height at *eight or nine days is evidence of a highly susceptible individual*. Between these extremes of reaction and susceptibility there are many intermediate responses and *degrees of immunity which follow a characteristic pattern*.

In order of degree of immunity which they indicate, the following reactions can be classified approximately as follows:

(1) *Immune Reaction*.—This occurs as a papule with a light surrounding erythema usually reaching its height within one or two days following the inoculation and then receding quite rapidly in size and reactivity. Individuals showing this type of reaction often have been previously vaccinated within a relatively short time.

(2) *Accelerated Reaction*.—In such individuals the immunity is less than in the preceding case; the reaction reaches its height in from three to five days and there is a vesicle rather than a papule with a marked erythema extending well out from the base of the vesicle. The entire area rarely extends over ½ to ¾ inch in diameter. Slight fever, malaise, chilliness, aching, local tenderness and slight enlargement of the draining lymph gland *frequently occur*. By some this type of reaction has been termed "vaccinoid."

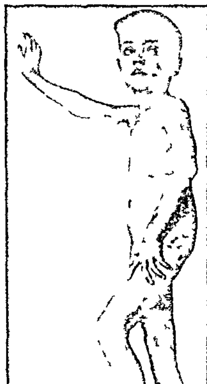
(3) *Primary Vaccination Reaction or Typical Take*.—In the typical "take" little is noted at the site of inoculation except for a punctate area of erythema until the fifth day, when a vesicle appears with a rapidly increasing erythema and induration about it. Usually the vesicle, erythema and induration increase up to the ninth day, when the total area involved ranges approximately from the diameter of a silver half dollar up to the diameter of a grapefruit or even at times beyond in adults. The vesicle itself, if the vaccination is properly performed, rarely exceeds ¼ to ½ inch in diameter, but the area of erythema and induration may not only extend in a wide circular areola but may reach out toward the draining lymph nodes to involve areas of skin many inches from the central vesicle. In certain instances where primary "takes" have occurred by mistake on the tips of the fingers, acute lymphangitis resembling that due to the hemolytic streptococcus may occur during the height of the reaction and extend well up the arm—*apparently the result of the tension produced* in such a restricted area. In the larger reactions, the draining lymph nodes are swollen and tender. Fever is usually present, *in infants at times reaching 104° or 105° F* and remaining at that elevation for several days. Extreme discomfort with chills, aching and localized tenderness is quite common. Also in such reactions small additional vesicles may occur about the periphery of the indurated area. As a result of the irritation and itching, infants will frequently scratch the vesicle and inoculate themselves elsewhere on the body at the site of open skin lesions or scratch marks. As the reaction subsides, the vesicle, which is typically umbilicated, becomes darker in color, with a deeper central crater and gradually changes into a hard black crust which falls off in several weeks. The remaining scar is bluish red at first and in time becomes a firm white area characteristically round and irregularly pocked.

The failure of an individual to react in one of the above manners is not an indication *of immunity, as is often incorrectly supposed*, but is rather an evidence in almost all instances of an inactive virus vaccine. In certain cases the lymph may have been washed

off with soap and water or possibly methyl alcohol or some other improper antiseptic may have been used for preparation of the site of inoculation but it is probable that in only rare instances does the child fail to react when the virus is active and applied properly on a dry site

Care of Reaction —Of primary importance in the care of the lesion resulting from the typical 'take' is maintenance of dryness and a free flow of air about the vesicle For this reason shields should never ing occurs, so that the gauze becomes attached to the vesicle sulfathiazole ointment 5 per cent may be applied to the vesicle at least twice daily following the usual cleansing with alcohol and a piece of gauze may be added as further protection for the clothing

Frequency of Vaccination.—Opinions vary as to the required frequency of revaccination but in general five to seven years may be considered a proper interval between vaccinations with the additional



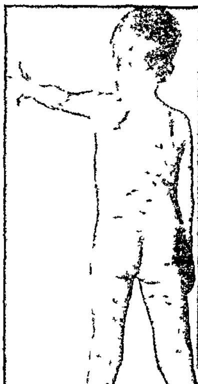


Fig 8—Hyperallergy expressed as roseola vaccinosa Note the marked area of the vaccination lesion on the arm (From the article on vaccinia by Dr Murray Cowie in 5th edition of Cecil s Textbook of Medicine)

be used In addition a relatively sterile surface may be maintained on the vesicle and on the entire area about the reaction by sponging them gently with alcohol and cotton at least twice daily being careful to leave the surface of the vesicle intact If a serous discharge occurs from the vesicle due to excessive tension or as more commonly occurs to trauma alcohol and cotton should be used three to four times daily and a loose piece of gauze attached to the clothing over the vesicle or attached to the skin by adhesive tape placed well outside the indurated area If a discharge sufficient to cause crust

provision that vaccination be performed whenever epidemics of smallpox are pending

Complications and Sequelae —The most dangerous complication of vaccination is that of pyogenic infection This results from neglect dirt scratching and other skin infections Such infection is usually of staphylococcic origin with cellulitis but hemolytic streptococci may at times be responsible and septicemia erysipelas or scarlet fever may also be seen Such infections increase the size and severity of the reaction considerably and result finally in a large and disfiguring scar

The additional necrosis caused by such complications is an excellent medium for the growth of tetanus bacilli Tetanus occurs less frequently now than formerly, but is still an important consideration where dirt and squalor prevail Under such conditions the use of tetanus toxoid for immunization should precede vaccination against smallpox The elimination of shields in the care of the usual take' has also eliminated much of the danger of tetanus

Scratching may cause secondary vesicles at distant points, particularly about the genitalia and face where severe scarring can occur A generalized vaccinia is seen at times in infants with eczema or some other generalized skin disease when it has been exposed to another vaccinated member of the household Umbilicated lesions may extend over most of the body with high fever and extreme toxemia In such cases lesions of the eye should be handled most carefully because of the danger of corneal perforation At times generalized urticaria roseola or purpura are seen when the reaction is at its height

Postvaccinal encephalitis is comparatively rare in the United States but occurs with greater frequency in England and Europe It usually appears about ten days to two weeks following the height of the vaccination reaction although it may be seen earlier or later The severity of this complication appears to be entirely unrelated to the severity of the 'take' The onset is generally abrupt with high fever disorientation and at times with coma or convulsions A stiff neck positive Kernig increase or absence of reflexes and positive Babinski are usually present Weakness and paralysis of the extraocular muscles are common as well as paralyses of the face pharynx, and limbs The white blood cells are increased in the spinal fluid as a rule, chiefly the lymphocytic although at first there may be an increase in polymorphonuclear cells The sugar and chloride of the spinal fluid ordinarily are not greatly altered but the protein is usually increased as is also the spinal fluid pressure The reflex control of the bladder and bowel is often disturbed The course of the disease is usually extremely stormy with either a rapid progression to death or an equally rapid improvement The mortality of this complication ranges from 30 to 40 per cent and even though rapid improvement occurs, residual mental retardation or spasticity may remain There is no specific therapy available other than lumbar punctures for relief of spinal fluid pressure and the proper orthopedic care of any paralyzed or spastic skeletal muscles

JOSEPH STOKES JR

MUMPS

(*Epidemic Parotitis*)

Definition —Mumps is a communicable disease characterized by swelling of the parotid and occasionally other salivary glands, fever and in adults a tendency to complications most frequently orchitis or meningo encephalitis

Etiology —Mumps is caused by a filtrable virus capable of infecting monkeys and possibly cats A parotitis transmissible in series was produced by Johnson and Goodpasture by injecting monkeys directly into Stensen s duct with rather large amounts of saliva collected from patients with mumps When an emulsion of the parotid glands of infected monkeys was sprayed into the throats of susceptible individuals this resulted in the development of mumps and the saliva of one of these patients produced a parotitis when inoculated into monkeys Those immune to mumps were not affected by such spraying Findlay and Clarke confirmed the results of Johnson and Goodpasture

Previously, a number of workers had described a variety of micro-organisms which they believed to be of etiologic significance, but these observations have not been confirmed Martha Wollstein injected filtrates of the salivary secretion of children and adults in the acute stage of the disease into the parotid glands and testicles of cats and produced inflammatory swellings which she considered to be mumps Her results however were less regular than those of Johnson and Goodpasture

Morbid Anatomy —Because of the low fatality there is little information available concerning the pathologic picture in the parotid gland in mumps Johnson and Goodpasture in reviewing the subject described the changes in the infected parotid

gland as consisting of an interstitial serous exudate, an interstitial fibrinous exudate catarrhal inflammation of the excretory ducts foci of hemorrhage an interstitial infiltration by leukocytes desquamation of the epithelial cells with a leukocytic infiltration of the tubules and edema of the glandular epithelium, an intense, interacinar vascular congestion marked periglandular edema and changes of early necrosis in the glandular epithelium'

In the experimental mumps of monkeys the changes were quite similar and cytoplasmic inclusions were described in the acinar cells Bloch observed that the cytoplasmic inclusions occurred in the absence of the mumps virus and therefore he did not consider them specific for the disease

Symptoms —*Incubation Period* —As a rule the incubation period is from seventeen to twenty-one days after exposure although some authors quote figures of fourteen to twenty five days Incubation periods of less than one week or as long as four weeks have been reported but these are quite unusual

Communicability —Close contact is usually necessary for the transmission of mumps and a relatively small proportion of children exposed contract the disease as compared with the incidence of infection in measles or chickenpox The virus is present in the saliva and is disseminated by droplet infection or mechanically as for example by contaminated hands The portal of entry of the virus is probably the mouth

Mumps affects persons of all ages but is most frequent between the ages of five and fifteen years The disease is infrequent in children under two years of age and infants are usually immune up to the eighth or tenth month However cases of mumps in both infants and newborn have been reported

The disease occurs in all parts of the world most commonly in epidemic form The climatic conditions seem to have little effect on the prevalence of mumps but the greater number of cases tend to occur in the winter and spring

The period of contagion of mumps is unknown but it is presumed to last from the beginning of symptoms until the disappearance of the swelling of the glands involved A few cases have been cited of infection by contact before symptoms were observed but this is extremely rare The usual custom is to isolate all cases for three weeks after the onset of symptoms Contacts are commonly quarantined for twenty-one days after exposure

Immunity —One attack ordinarily confers immunity for life Second and third attacks have been observed but these observations have been questioned by some Macleod in an analysis of 694 cases of mumps in adult males noted that seventeen stated that they had had mumps previously and one said that this was his third attack

Mode of Onset —The severity of mumps varies greatly and in mild attacks the first symptom is usually pain below the ear, followed rapidly by swelling of the parotid gland and a rise of temperature to about 101° F In severe cases there may be a prodromal period of twenty four to forty-eight hours characterized by fever malaise chilliness anorexia and headache and after the appearance of parotitis the temperature may rise as high as 103° to 104° F The enlargement of the parotid gland usually progresses reaching its maximum on the second day The enlarged gland is as a rule firm and somewhat elastic frequently both glands are involved although the second may not be affected for several days after the first The swelling is generally below and in front of the ear and may extend back to the sternomastoid muscle the lobe of the ear being somewhat elevated and in the center of the swollen area The submaxillary and sublingual glands may at times be involved and in rare cases may be affected without the parotid gland

Clinical Course —The temperature and swelling generally reach their maximum on the second day after which they gradually return to normal The average duration of symptoms is seven days in uncomplicated cases The disease may however last much longer and swelling has been known to persist for a number of weeks Relapses after twelve to fifteen days have been described as occurring in about 10 per cent of the cases

Complications —*Orchitis* is extremely rare before the age of puberty probably not more than 1 per cent In epidemics among adults the incidence is much higher varying

in different reports from 10 to 50 per cent and averaging about 18 per cent

The onset is usually between the fifth and tenth day after the parotid swelling, and is characterized by a rise in temperature pain and swelling in the affected testicle, and frequently by general malaise, chilliness discomfort in the inguinal region and occasionally nausea The swelling progresses for two or three days and then gradually subsides returning to normal in seven to ten days Occasionally the course may be much longer and more severe The inflammation is in the testicle usually and not in the epididymis Only one testicle is involved as a rule but both may be affected Rarely orchitis may be the only manifestation of mumps

Atrophy of the testicle as manifested by a reduced size of the gland, is rather frequent apparently taking place in 40 to 60 per cent of the cases Impotence and sterility, although they do occur are not common

Meningo encephalitis is not of uncommon occurrence although its frequency is difficult to determine An incidence as high as 23 per cent has been reported in some epidemics All ages are affected and there is no evidence that sex plays a part

The symptoms of meningo encephalitis begin toward the end of the first week of illness There is a sudden rise of temperature, headache stiffness of the neck and a positive Kernig s sign are the most frequent manifestations Delirium may occur but is not the rule The spinal fluid is under increased pressure is clear or slightly opalescent and shows a pleocytosis composed largely of mononuclear cells which may at times be as high as 1200 although this is exceptional

The prognosis is good Deaths have been reported but they occur only rarely In sixty cases observed in the meningitis division of the Bureau of Laboratories, New York City Department of Health no deaths occurred

The severity may vary greatly Finkelstein reported six cases who had only a slight rise of temperature for twelve to twenty four hours and no clinical signs of meningo encephalitis but who nevertheless showed a pleocytosis on lumbar puncture This would tend to show that involvement of the central nervous system is more frequent than is commonly recognized

Deafness is of occasional occurrence and may be permanent This is assumed to result from inflammatory involvement of the labyrinth

Pancreatitis, nephritis mastitis and involvement of the lacrimal glands are occasional complications

Suppuration of the parotid gland has been reported in less than 1 per cent of the cases and is attributable to secondary infection

Diagnosis —During epidemics diagnosis is simple the long incubation period characteristic parotid swelling, and clinical course being sufficient It is only during epidemics that cases in which only the submaxillary glands are involved can be diagnosed

The blood picture may at times be of assistance There is an increase in white blood cells with an absolute and relative lymphocytosis The pulse is frequently slow and may be 50 to 60 per minute

Differentiation must be made between parotitis caused by bacterial infection which is usually secondary to some other diseases cervical adenitis secondary to septic sore throat diphtheria or scarlet fever, tuberculous adenitis Hodgkin s disease This is usually not difficult

Prognosis —The prognosis is good, and fatal terminations are extremely rare—less than 1 per 1000 Complications are uncommon in childhood and are more frequent after the age of puberty

Treatment —Rest in bed is desirable so long as fever or swelling persists The mouth should be kept scrupulously clean in order that secondary infection of the parotid gland may not occur Ample fluids and a soft diet should be given while fever is present Mild sedation may be necessary

Orchitis is treated by support of the testicles Local applications may alleviate discomfort It is said to occur more frequently in patients who have not been confined to bed

Meningo encephalitis is treated symptomatically Lumbar puncture usually relieves headache, but sedatives may also be required

Prophylaxis—Isolation for three weeks is customary Convalescent serum injected in a dose of 2 to 8 cc has been used for passive protection within six days after exposure The results are suggestive but the available information is not adequate for proof of the effectiveness of this procedure

PSITTACOSIS

Definition—Psittacosis is a specific infectious disease of parrots parrakeets love birds and other members of the parrot family The malady is highly communicable to man

History—Ritter 1880 first adequately described psittacosis as a disease entity in man designated it "pneumotyphus and associated it with the presence of sick birds in the patient s home Nocard 1892 discovered *Bacillus psittacosis* which subsequently was shown to be identical with *B aertrycke* and not the cause of psittacosis Bedson and others 1930 showed that the etiologic agent of psittacosis is filtrable Levinthal 1930 found minute coccoid bodies of diagnostic importance in infectious material Krumwiede 1930 showed that white mice are susceptible Rivers and Berry 1930 1932 experimentally induced psittacosis pneumonia in monkeys and devised a method using white mice instead of birds whereby one may test for the presence of psittacosis virus in a patient s sputum

Epidemiology—Man usually contracts the disease from members of the parrot family canaries or finches Recently it has been shown that fulmars chickens and pigeons are subject to natural infection with psittacosis virus These birds when infected can pass the disease to human beings but are less dangerous in this respect than are members of the parrot family A carrier state probably exists in birds Psittacosis never pandemic in nature manifests itself in a given population by isolated household epidemics Transmission of the disease from man to man occurs, but not frequently Both sexes and all ages are susceptible Children however appear to be more resistant than adults The virus found in the nasal discharges and droppings of infected birds and in the sputum of patients is stable withstanding prolonged drying and enters man through the mucous membranes of the upper respiratory tract

Etiology—The inciting agent is filtrable and has not been shown capable of multiplication on ordinary media The minute coccoid bodies described by Levinthal and subsequently shown by Bedson to be specifically agglutinated by immune serum are considered by many investigators to represent the virus

Morbid Anatomy—In the parrot and the mouse the lungs are rarely involved The liver is enlarged and studded with areas of necrosis The spleen the normal architecture of which is destroyed is enlarged and contains areas of focal necrosis In man and the monkey the striking feature of the disease appears in the lungs and is characterized by a patchy consolidation starting near the hilum and spreading toward the periphery of the organ Only slight if any involvement of the pleura is seen Bronchitis is not a pronounced feature In stained sections the alveolar walls show a marked cellular infiltration and the alveolar spaces are filled with mononuclear cells and fibrin. In fact the cellular infiltration or proliferation of cells in the alveolar walls including an active proliferation of the alveolar epithelium giving rise to rows of cuboidal cells lining the alveolar spaces is characteristic of psittacotic infections of the lungs Congestion and thrombosis of capillaries occur and often the alveolar walls become necrotic If the lungs are secondarily invaded by pneumococci or streptococci the pathologic picture is altered accordingly The liver may show fatty degeneration with areas of focal necrosis The spleen may or may not be enlarged and at times shows hyaline de

generation of the smaller vessels No specific changes have been found in the brain

Incubation—The incubation period in the majority of instances is eight to fourteen days

Symptoms—The onset of the disease is usually abrupt with malaise anorexia headache, backache photophobia and chills Headache, restlessness, insomnia, delirium, typhoidal state, nonproductive cough, constipation with abdominal distention and tenderness, are as a rule present during the height of the infection A few cases exhibit a diarrhea Epistaxis occurs in about 25 per cent of the cases In a number of instances rose spots have been seen The temperature rises rapidly and after a period of continued elevation begins to fall by lysis during the second or third week The pulse is relatively slow Pleural pain is usually absent and the respiratory rate is only slightly increased A decided increase in the pulse and respiratory rate indicates a bad prognosis Only rarely does consolidation of the lungs fail to make its appearance It starts at the hilum and spreads toward the periphery Physical signs may appear slowly but x ray examinations indicate that the lung involvement comes early in the course of the infection The x ray picture is not unlike that seen in influenzal pneumonia As a rule the cough is nonproductive Sputum when produced is usually tenacious but not rusty A few patients however bring up large amounts of sputum over long periods of time White blood counts reveal a slight leukocytosis at the onset of the infection with a tendency toward a leukopenia later Relapses occur Phlebitis is not an infrequent complication Convalescence is slow and tedious

Diagnosis—An atypical pneumonia accompanied by slow respiratory and pulse rates, a normal or low white blood count an absence of pleural pain an intense and persistent headache and a typhoidal state in an individual associated with birds, particularly members of the parrot family should suggest the possibility of psittacosis The disease is most likely to be confused with typhoid fever influenza or atypical pneumonias not caused by the virus of psittacosis Typhoid fever is excluded by negative blood and stool cultures and a negative Widal reaction Results of the mouse test for the presence of psittacosis virus in the sputum indicate whether or not one is dealing with a psittacosis pneumonia The complement fixation reaction is a diagnostic aid

Prognosis—The mortality rate, given as 35 to 40 per cent, is probably too high inasmuch as a number of mild cases may have been overlooked Individuals under thirty years of age are less likely to die than are older ones

Prophylaxis—Avoid birds likely to be infected The virus is in the sputum and this fact should be borne in mind by those caring for psittacosis patients

Treatment—The treatment is symptomatic

LYMPHOGRANULOMA INGUINALE

(*Climatic Bubo Nicholas Favre Disease Lymphopathia Venereum*)

Definition—Lymphogranuloma inguinale is a specific infectious venereal disease characterized by a transient primary lesion often

overlooked followed by a subacute lymphadenitis with suppuration fistulae and eventual cicatricial healing

Incidence—Formerly thought to be largely a disease of the tropics particularly affecting males it is now known to be endemically prevalent in temperate as well as tropical zones and to occur in both sexes though in somewhat different clinical forms

Epidemiology—The usual method of infection is by sexual intercourse but the infection may be contracted by nonvenereal contact and has occurred following accidental inoculation

Etiology—Lymphogranuloma inguinale is caused by a filtrable virus which can be isolated from the lesions and transmitted experimentally to monkeys guinea pigs and mice (Hellerström and Wassen) Elementary bodies similar to those of vaccinia are found in pus from the lesions (Coles)

Pathology—The pathology varies with the intensity and duration of the infection In general it consists of an inguinal and pelvic lymphadenitis Multiple abscesses develop in the affected lymph nodes and discharge through fistulous openings Subsequently scar tissue formation ensues and may lead to rectal stricture and elephantiasis of the external genitalia Histologically the lymph nodes and surrounding tissues present the picture of a subacute or chronic infectious granuloma

Symptoms—The incubation period from the time of exposure to the onset of adenitis is ten to fifty days Some time during this period an evanescent primary lesion on the prepuce or glans may be noted in males In females primary lesions of the external genitalia are rare being commoner on the vaginal wall or cervix The adenitis usually first involving the inguinal lymph nodes in men and the pelvic nodes in women begins insidiously and runs an indolent course The onset may be accompanied by mild systemic symptoms of malaise headache anorexia and moderate fever With the development of periadenitis the overlying skin becomes attached and dark red or purplish Areas of softening appear in the nodes and eventually discharge a seropurulent fluid through fistulae which may drain for weeks or months Arthritis is reported to occur in many cases In women with pelvic and perirectal adenitis the condition may pass unrecognized or anal fistulae with purulent discharge from the rectum and painful defecation may herald the onset Since these symptoms may simulate those of ulcerative colitis a Frei test is desirable in patients with this disease Late sequelae due to contractile cicatricial healing are rectal strictures and elephantiasis of the scrotum and penis in males or of the vulva and perianal region in females Indolent ulcerative lesions about the genitalia in women a condition known as esthiomene may complicate the picture

Diagnosis—The diagnosis depends primarily upon the history and clinical picture It has been greatly facilitated by the intra

Fig 9—Lymphogranuloma inguinale Unilateral involvement 5 days after appearance of inguinal adenitis (Courtesy of Howard and Strauss New England Journal of Medicine)

dermal test described by Frei which should be used in all suspected cases In general the Frei test for cutaneous sensitivity is specific and becomes positive by the time periadenitis has developed Since it apparently remains permanently positive it must be kept in mind that a positive test does not necessarily permit a positive diagnosis of the lesion under consideration but may be only an indication of a previous infection Hyperglobulinemia accompanies the active stages of the infection

Treatment—No specific cure is at present available The treatment of choice would appear to be surgical extirpation of the affected nodes prior to suppuration and fistula formation combined with rest and medical

supportive measures Chemotherapy with the sulfonamide derivatives is reported to be helpful in some cases

FOOT AND MOUTH DISEASE

(*Aphthous Fever Epizootic Aphthae Epizootic Stomatitis*)

Definition —Foot and mouth disease is a contagious malady of cloven footed animals *e g* cattle pigs sheep and goats Guinea pigs and hedgehogs are susceptible to experimental infection Upon rare occasions man becomes infected and the disease in the human host is characterized by a febrile reaction and a vesicular eruption in the mucous membrane of the mouth which at times also involves the skin of the hands and feet

Incidence —In many parts of the world the disease is enzootic and often becomes epizootic Lower animals in the United States are relatively free from the malady, consequently, human beings in this country are not frequently exposed to it In fact man is not highly susceptible as is evidenced by the fact that nine volunteers failed to develop signs of the disease following inoculation of the virus into their soles and palms Nevertheless it has been definitely shown by means of inoculation of vesicular material from patients into guinea pigs that at least five human beings have had foot and mouth disease Man usually contracts the disease from infected low animals or from the products of such animals, transmission from man to man is unknown

Etiology —Loeffler and Frosch showed that the etiologic agent is a filtrable virus Their findings have been abundantly confirmed and now it is known that the virus is exceedingly small possessing a diameter of 8 to 12 millimicrons The causative agent is found in the milk butter saliva urine feces, hides and meat from infected cattle

Symptoms —After an incubation period of two to fourteen days the patient develops fever and vesicular lesions in the mucous membrane *of the mouth and on the lips* Similar lesions may appear on the soles palms *and the interdigital skin of the fingers* and toes Within a few days the fever sub*sides and the lesions heal without the formation* of scars

Diagnosis —*All vesicular lesions in and* around the mouth are not caused by the *virus of foot and mouth disease A correct* diagnosis can be arrived at only by means of *tests properly conducted in a susceptible* host *e g* the guinea pig One should remember *however that in the United States per*mission to make such tests must be obtained *from the Bureau of Animal Industry in* Washington

Prognosis —*In man the disease is mild* and complete recovery is the rule

Prophylaxis and Treatment —*In countries where the disease is enzootic or epizootic pasteurized milk or milk products* should be used Treatment is symptomatic

LYMPHOCYTIC CHORIOMENINGITIS

Definition—Lymphocytic choriomeningitis is an acute disease of man characterized by a lymphocytic reaction in the meninges monkeys and mice are also susceptible to natural infection guinea pigs are susceptible to experimental infection

Incidence—The disease has been definitely recognized for only a short time but within that period the virus causing it has been recovered from a number of patients in America and abroad

Etiology—A medium sized virus has been shown to cause the malady It has been isolated from the spinal fluid and blood of patients during the acute stage of the disease and antibodies against the virus which develop relatively slowly have been demonstrated in the blood of recovered patients Spinal fluid and blood (1–2 cc) from patients suspected of having the disease should be injected subcutaneously into guinea pigs If virus is present the pigs will develop a fever within seven to nine days and will usually die within twelve to eighteen days Passages from pig to pig can be made by means of blood or an emulsion of the brain

Symptoms—A period of generalized pains and malaise followed by severe persistent headache nausea and vomiting nuchal rigidity Kernig s sign and fever accompanied by a relatively slow pulse are the symptoms and signs usually encountered The white blood cell count is not particularly abnormal Lumbar punctures reveal spinal fluids under increased pressure containing a normal amount of sugar an increased amount of protein and an increased number of cells (200–1700 per cubic millimeter) which are predominantly lymphocytes The fever usually disappears within a week at which time the patient begins to feel much better but the cell count in the spinal fluid may return to the normal level much more slowly

Pathology—The pathologic picture in human beings is as yet not well defined The virus however produces a lymphocytic choriomeningitis and an interstitial pneumonia in monkeys mice and guinea pigs

Diagnosis—In 1925 Wallgren described what he considered a clinical entity and designated it acute aseptic meningitis' There are reasons however to believe that all cases that conform to Wallgren s criteria for acute aseptic meningitis' are not caused by one kind of virus Some undoubtedly are induced by the virus of lymphocytic choriomeningitis and should be removed from the group of cases known as acute aseptic meningitis and placed in a separate category designated as lymphocytic choriomeningitis Neutralization and complement fixation tests are diagnostic aids

Prognosis—Individuals afflicted with this disease rarely if ever die complete recovery is the rule but an occasional patient experiences sequelae

Treatment—Repeated lumbar punctures and intravenous injections of hypertonic solutions of glucose seem to relieve the headache which is a very prominent symptom of the malady

HYDROPHOBIA

(*Lyssa Rabies*)

Definition—Hydrophobia is an acute infectious virus disease usually transmitted in the saliva of a rabid animal It is characterized by a variable incubation period by symptoms of irritability of centers in the brain and by psychic excitation and hyperesthesia followed by paralysis and death

History—Rabies was described by Aristotle Celsus and Galen In 1804 Zinke demonstrated its infectious nature by successfully inoculating animals with the saliva of rabid dogs

In 1881 Pasteur proved that the virus is always present in the central nervous system and can be transmitted by subdural inoculation with the brain of a rabid animal In 1884 he showed that animals can be protected by the subcutaneous injection of spinal cord containing the virus which has been modified by passage through a series of rabbits and attenuated by drying

Incidence—The disease occurs in all countries and climates and at all seasons of the year All mammals and most warm blooded animals are susceptible, but responsibility for its presence rests on the dog

Etiology—The virus is filtrable, and is altered and destroyed by chemicals and by physical agents as heat drying and sunlight

It enters through a bite, or when the saliva comes in contact with an open wound or with the mucosa of the lips or nose The virus travels in the nerves to the brain multiplies there and passes out along the efferent nerves of the salivary glands into the saliva

Morbid Anatomy—At autopsy the only gross change found is a marked congestion of the vessels in the meninges and the brain In most cases a microscopic examination of the cornu ammonis shows the presence of characteristic inclusion bodies described by Negri A positive diagnosis of rabies is made whenever these are present Unfortunately it is *not* always possible to demonstrate these structures hence the failure to find them does not exclude the possibility of rabies

Throughout the brain there may be found a perivascular infiltration of small round cells and in the gasserian and sympathetic ganglia there is usually an infiltration of endothelial cells with destruction of the nerve cells However these changes are found in other diseases

Incubation—The incubation period varies from ten days to two or more years The average is fifty to sixty days In dogs it is usually between fifteen and thirty days but may be as long as a year or more

The length of this period is influenced by the location and extent of the bite and by the species of the biting animal Since the virus travels along the nerves it reaches the brain more quickly and symptoms develop earlier when the bites are on the face and head than when the injuries are on the hands, likewise these latter have a shorter period than bites on the feet and legs

Bites of wolves and other wild animals are more dangerous than those of dogs partly because these animals, being ferocious, bite more deeply, and partly because passage of the virus through such carnivora increases its infectivity

In this country rabies in man is usually due to the bite of a dog Cats wolves skunks and other animals make up less than 10 per cent of infective agents It is estimated that 10 to 15 per cent of all persons bitten will develop hydrophobia unless immunized The mortality from bites on the face and head will average 60 to 70 per cent, those on the hands 15 to 20 per cent those through clothing 1 per cent The more extensive the injury the greater the mortality Contact in the absence of a wound is rarely followed by rabies Alcoholism exposure to extremes of heat and cold fatigue and fear are factors in the development of the disease

Symptoms—In *dogs* there are two types of the disease furious and dumb, but these two forms may merge or appear at different stages in the same animal

In the *furious* type one of the first symptoms is an altered disposition The gentle dog becomes morose does not bark joyously seeks seclusion hides and refuses food Frequently it becomes more friendly than ever refuses to leave its master s side tries to lick his hand and face and redoubles its affection Twelve to forty eight hours later it grows unnaturally restless comes and goes incessantly rests for a moment lying down then jumps up brusquely moves to another place in evident agitation and again resumes its restless movements It may make no effort to bite and may obey all commands, but is unable to remain quiet and acts as though under a strange and unnatural compulsion Short periods of repose are followed by increased agitation Irritation over any restraint is marked Strangers are attacked without warning

As the disease progresses it snarls viciously barks and growls menacingly at imaginary objects turns suddenly as if to defend itself It chases and bites animals around the house and farm the cats dogs poultry horses cows and other domestic animals with which it had previously lived

peacefully The animal if housed is agitated and excited scratching tearing and upturning its bedding gnawing at furniture and grabbing viciously at any object pointed at it If free, it leaves the house and travels long distances biting such animals as it may encounter though not going out of its way to seek a quarrel and not remaining near its victims It attacks and passes on At last haggard emaciated it falls from the oncoming paralysis or unsteadily makes its way back to its home to die

The so-called dumb or paralytic type is very common (20 per cent), but is usually unrecognized except by veterinarians The stage of excitement and irritability is absent or unnoticed The attack is more fulminating the progress more rapid From the beginning the animal is evidently ill and anxious but not excitable

Paralysis may begin in any muscle or group though usually the first noted is in the lower jaw It cannot close its mouth the tongue protrudes saliva flows in excess Paralysis rapidly extends to other parts of the body and death follows in two or three days It is this condition which leads sympathetic people to imagine the dog has a bone in its throat and to try to remove it In doing so their hands become covered with saliva

The disease occurs in dogs at all times of the year but more persons are bitten in the summer because at this season more men women and children are on the streets or out of doors

In man the disease is frequently ushered in with a short prodromal period of mental depression a feeling of impending danger insomnia Ungovernable restlessness seizes the patient Melancholia is common Hyperesthesias of the skin to changes of temperature and especially to currents of air and increased sensitiveness to sound and light mark the progress of cerebral irritation A patient weighed down with terror often becomes maniacal the restlessness increases to uncontrollable agitation An excessive flow of thick tenacious saliva pours over the face and neck and becomes smeared on his hands and clothes and over the bedding and floor Periods of rage are followed by moments of calm in which the patient usually shows anxiety for the safety of those around him and warns them of the approach of another crisis Convulsions are brought on by the least irritation and by the slightest current of air Aerophobia is one of the most characteristic symptoms of rabies Blowing the breath on the neck of a patient often precipitates convulsions and is valuable in differentiating this disease from hysteria The slightest breeze brings on respiratory difficulties the breath comes in spasms dyspnea is extreme and there are epileptiform seizures or tetanic rigidity

The symptom which gives to the disease its common name *hydrophobia* appears as a rule twenty four to forty eight hours after the onset It is rarely absent This symptom due to the reflex irritability of the center of deglutition gives rise to those laryngeal spasms so agonizing to the patient and so distressing to the attendants as to justify the universal dread of the disease When the victim lifts the glass to his lips there is an immediate viselike contraction of the muscles of deglutition with an excruciatingly painful spasm of the glottis and pharynx The body trembles with convulsive movements the jaws are clenched respiration is impossible The patient feels that he is being strangled to death and may die suddenly during the spasm After several attempts to drink the pain is so terrible that despite the intense thirst he cannot be induced to try to swallow liquids and the sight of water or mention of the word brings on an attack Death occurs as a rule after two or three days from cardiac or respiratory failure

A paralytic form occurs in man in which symptoms of cerebral irritation are wanting After an onset with high fever neuralgic pains in the region of the bite are followed by weakness and paresis of the muscles of this part Paralysis becomes general and death occurs in from three to five days

Diagnosis —In man the diagnosis is rarely difficult The history of exposure the length of the incubation period and the clinical symptoms serve to differentiate it from tetanus Fear of the disease may result in a hysterical state closely simulating the real disease These persons are relieved by suggestion or proof that they have not been exposed Hysteria is rarely fatal A microscopic examination of the brain and the in

oculation of animals will establish the diag nosis in doubtful cases

Prognosis—Once the symptoms have developed, death is inevitable The pain and excitement are controlled by large doses of sedatives chloral morphine coal tar preparations, chloroform or other anesthetics

Treatment—This is the destruction of the virus at the time of injury and preventive immunization

Local—The wound should be mechanically cleansed and cauterized with pure carbolic acid followed immediately with 95 per cent alcohol Nitric acid is advocated, but its use is more painful and probably no more effective Cauterization cannot be relied upon to destroy all the virus but its use has been shown to result in a prolonged incubation period The next and most important step is to determine whether or not the biting animal is rabid It should never be killed unless to protect others until the diagnosis can be confirmed or excluded by observation while alive It is not always possible to find microscopic evidence of rabies in the brain especially if the animal is killed *early in the disease The saliva of a dog may* be infectious from four to six days before the appearance of symptoms if therefore the animal appears normal and remains so for a period of ten to fourteen days the possibility of infection may be dismissed

Any biting animal should be suspected of being rabid until proved otherwise An animal that cannot be confined and observed should be regarded as rabid

General—In all cases where the animal is known to be rabid or when it cannot be examined the patient should receive Pasteur treatment as promptly as possible The value of the Pasteur treatment for rabies has been widely accepted but recently some doubt as to its efficacy has been raised by Webster who bases his misgivings on both experimental and statistical grounds While there may be some scientific basis for this skepticism the majority of immunologists still retain their faith in the Pasteur treatment and a practitioner would not be justified at the present time in advising his patient against its use

The mortality of those promptly treated is less than 1 per 1000 Deep or lacerating wounds on the head or hands require the so called intensive treatment' in which larger amounts of vaccine are given

No preparation of the vaccine is invariably effective or entirely free from dangerous sequelae In very rare cases the injection of the vaccine is followed by severe and sometimes fatal paralysis This appears to be due to an individual sensitiveness to rabbits brain and cord and is not the result of an infection by the vaccine

Because of this danger rabies vaccine should not be given if it is evident that the offending animal is not rabid and if it continues to act normally while under observation

Suppressive Measures—The destruction of all ownerless dogs and the temporary muzzling or restraint of the rest by their owners is the one and only method of eradicating this disease This has proved successful in England and in the Scandinavian countries where the disease once as common as it is here has completely disappeared

The immunization of dogs is still in the experimental stage Webster found no appreciable immunity following the single injection of phenolized canine vaccine

POLIOMYELITIS

(*Infantile Paralysis*)

Definition—A common acute virus disease which may give rise to myelitis often resulting in flaccid paralysis of various groups of muscles It is prone to appear in epidemic form particularly in the summer time and children are more susceptible than are adults It is characterized by sudden onset with a brief period of fever and malaise which is the extent of the clinical picture in many of the cases

History—Reference to conditions which may have been poliomyelitis dates from earliest times but no descriptions of this disease have been found in medical literature prior to the end of the 18th century At this

time mention of acute paralysis in childhood was made in England by Michael Underwood in his textbook on diseases of children During the subsequent fifty years there are several descriptions of poliomyelitis the best being that by the German orthopedist Heine (published in 1840) who was apparently the first to understand the nature of this disease Strangely enough the epidemic character of poliomyelitis did not receive emphasis until Medin's work appeared in Sweden in 1890 From that time forward the disease ceased to be a curiosity and became in some countries a periodic scourge The principles of its epidemiology were first reviewed by Medin's pupil Wickman who published his monograph in 1908 the same year in which Landsteiner discovered the virus Three years later Kling and his associates in Stockholm laid the foundation for the more modern types of clinical investigation in poliomyelitis They were also responsible for pointing out the intestinal phases of this disease

Etiology —The virus of poliomyelitis has sufficiently distinct properties to permit its identification with considerable accuracy Its size estimated at approximately 10 to 15 millimicra marks it as one of the smallest filtrable viruses In comparison with many bacteria it is quite stable remaining viable at ice-box temperature in aqueous suspensions of feces for months and similarly in pieces of infected spinal cord stored in 50 per cent glycerine for years It can also survive in weak solutions of phenol and in high concentrations of ether, but is readily destroyed by oxidizing agents such as hydrogen peroxide potassium permanganate by ultraviolet rays and by heating for a short period of time to a temperature of 55° C Its resistance to chlorine has not been accurately determined but probably the amount of chlorination adequate for killing enteric bacteria in water may not suffice to destroy the virus of poliomyelitis

Another characteristic of this virus is its narrow host range for it is pathogenic only for certain monkeys and chimpanzees although perhaps in some instances for certain rodents—notably the eastern cotton rat As with other neurotropic viruses a number of different strains have been described An appreciation of this multiplicity of strains is important when one comes to an estimate by neutralization tests of immunity to this disease—both in animals and in man As a rule such tests are not very practical nor has it yet been possible to demonstrate specific immunologic reactions by means of precipitin tests complement fixation tests or cutaneous tests such as are used with many other infectious diseases This has seriously limited the study of human immunity to poliomyelitis

Epidemiology —Children are more susceptible than adults and in this respect poliomyelitis resembles such common diseases as diphtheria or measles But unlike diphtheria and measles poliomyelitis does not seem to be a respiratory disease How the virus of poliomyelitis enters the human body is still a matter of conjecture but it is unlikely that it gains access to the central nervous system solely by way of the olfactory bulbs It may penetrate through a number of possible portals including the mucosa of the oral cavity the lower gastrointestinal tract, or conceivably the skin Once in the body the virus shows affinity for two areas in particular (1) the intestinal tract (viz the lower ileum), where it may survive with or without the production of myelitis and (2) certain areas of the central nervous system

Regardless as to how the virus enters the body one of its major portals of exit is through the gastro intestinal tract A convalescent patient may harbor the virus here for months but usually it is demonstrable in the feces only for about three weeks after an acute attack *Healthy carriers* have also been described and Francis and his co workers have presented circumstantial evidence that healthy children may carry the virus for a month or more prior to their acquisition of the disease As a rule these carriers (both convalescent and healthy) are children under the age of six years The part which they may play in the general spread of the disease is unknown Dissemination of the virus might therefore result from direct human contact (which is the most commonly accepted view) or from contaminated objects including food An extra human reservoir of the virus in the form of infected insects (notably flies) mammals or birds is also a distinct possibility although the virus has been demonstrated in nature only in the first of these two groups

Summer weather and environmental factors are important influences in that epidemics are more apt to occur in the summer and early fall than at other times of the year and they are particularly prone to flourish in suburban or rural surroundings They are uncommon in institutions or in

oculation of animals will establish the diagnosis in doubtful cases

Prognosis—Once the symptoms have developed, death is inevitable The pain and excitement are controlled by large doses of sedatives chloral morphine, coal tar preparations chloroform or other anesthetics

Treatment—This is the destruction of the virus at the time of injury and preventive immunization

Local—The wound should be mechanically cleansed and cauterized with pure carbolic acid followed immediately with 95 per cent alcohol Nitric acid is advocated but its use is more painful and probably no more effective Cauterization cannot be relied upon to destroy all the virus but its use has been shown to result in a prolonged incubation period The next and most important step is to determine whether or not the biting animal is rabid It should never be killed unless to protect others until the diagnosis can be confirmed or excluded by observation while alive It is not always possible to find microscopic evidence of rabies in the brain, especially if the animal is killed early in the disease The saliva of a dog may be infectious from four to six days before the appearance of symptoms, if therefore the animal appears normal and remains so for a period of ten to fourteen days the possibility of infection may be dismissed

Any biting animal should be suspected of being rabid until proved otherwise An animal that cannot be confined and observed should be regarded as rabid

General—In all cases where the animal is known to be rabid or when it cannot be examined the patient should receive Pasteur treatment as promptly as possible The value of the Pasteur treatment for rabies has been widely accepted but recently some doubt as to its efficacy has been raised by Webster who bases his misgivings on both experimental and statistical grounds While there may be some scientific basis for this skepticism, the majority of immunologists still retain their faith in the Pasteur treatment and a practitioner would not be justified at the present time in advising his patient against its use

The mortality of those promptly treated is less than 1 per 1000 Deep or lacerating wounds on the head or hands require the so called 'intensive treatment in which larger amounts of vaccine are given

No preparation of the vaccine is invariably effective or entirely free from dangerous sequelae In very rare cases the injection of the vaccine is followed by severe and sometimes fatal paralysis This appears to be due to an individual sensitiveness to rabbit's brain and cord and is not the result of an infection by the vaccine

Because of this danger rabies vaccine should not be given if it is evident that the offending animal is not rabid and if it continues to act normally while under observation

POLIOMYELITIS

(*Infantile Paralysis*)

Definition—A common acute virus disease which may give rise to myelitis often resulting in flaccid paralysis of various groups of muscles It is prone to appear in epidemic form particularly in the summer time, and children are more susceptible than are adults It is characterized by sudden onset with a brief period of fever and malaise which is the extent of the clinical picture in many of the cases

History—Reference to conditions which may have been poliomyelitis dates from earliest times but no descriptions of this disease have been found in medical literature prior to the end of the 18th century At this

not been given) Fever is almost universal it is generally over 100° F lasting from one to four days Occasionally there is pain in the back, and occasionally a stiff neck but in general the physical signs are indefinite

In a typical *paralytic case* the onset and the clinical picture for the first two or three days are similar but the disease usually lasts longer with fever of from three to ten days —although generally not more than six In almost half of the cases there may be two bouts of fever, with myelitic symptoms confined to the second bout Early evidence of central nervous system involvement is indicated by stiff neck as a cardinal symptom and with it there may be fretfulness or restlessness apprehension yawning drowsiness and even stupor Pain in the limbs twitching and sensitivity to touch and pressure should be carefully noted as they may be the forerunners of paralysis The later days of fever mark the period in which signs of meningitis and myelitis may become more pronounced and in which flaccid paralysis may appear with considerable rapidity Muscle weaknesses may vary from quick fatigability to complete paralysis During this period of active myelitis retention of urine and constipation are not uncommon particularly when severe paralysis of the lower extremities and abdomen is present

Different clinical pictures arise depending on the region of involvement in the spinal cord and brain Thus we are accustomed to speak of *bulbar poliomyelitis* and the *encephalitic form of poliomyelitis* as well as *paralytic poliomyelitis* But it is seldom that the disease picture is limited solely to one of these various types With the bulbar type which occurs when the medullary centers are involved and is one of the most serious forms of the disease the first indications may be a report by the parents that the child s voice has a nasal tone or that there is difficulty in swallowing sometimes resulting in fluid being extruded from the nose With progression the inability to swallow becomes more serious and mucus and saliva accumulate in the throat Attempts to drink water cause coughing and gasping As the disease progresses the patient often becomes disoriented and comatose Attempts to examine the throat lead to choking and resistance

Diagnosis —There is no diagnostic test which can be efficiently applied in the early stages of poliomyelitis for the initial symptoms are apt to be nonspecific in character but headache, stiffness of the neck and/or the back are the most important symptoms Almost as important as the symptoms, are the circumstances under which they are found viz one should be concerned about poliomyelitis when the above symptoms occur during the summer or early fall or during epidemic times Under these circumstances a cardinal sign is fever that is fever higher than 101° F which is otherwise unexplained When poliomyelitis is suspected the neck and spine should be carefully examined viz place the child in a sitting position on the floor with the knees spread apart and press the head down between the knees Kernig s sign may be uninformative

Vigilance (not to be carried to the extent of daily exhaustive complete muscle tests) should be used for the early detection of weakness in muscles groups of muscles or limbs The reflexes may be erratic and normal reflexes may be found even while a patient is developing or has developed paralysis At first however the reflexes may be hyperactive becoming diminished or absent with surprising rapidity as weakness develops The physical examination should also include a search for ocular palsy facial palsy changes in the character of the voice paralysis of the soft palate and changes in the state of the respiratory and abdominal muscles

The *lumbar puncture* may be of considerable diagnostic aid but the findings are not pathognomonic In all cases in which there are well marked clinical signs of meningitic involvement and this includes both paralytic and nonparalytic cases the cell count is apt to be increased ranging from 15 to 150 cells or even many more They are largely mononuclear cells (50 per cent to 95 per cent) but cases with 80 per cent polynuclears in the spinal fluid may occur In a greater per cent of cases there is an increase in globulin However in the majority of abortive cases and occasionally even in the paralytic case the spinal fluid may be normal

In the acute and early stages the blood

homes for children, but are not infrequently seen as small outbreaks in summer camps In nature the virus has been isolated from sputum from human feces, from a privy, from sewage and from flies, and it may be far more widespread than these sites indicate

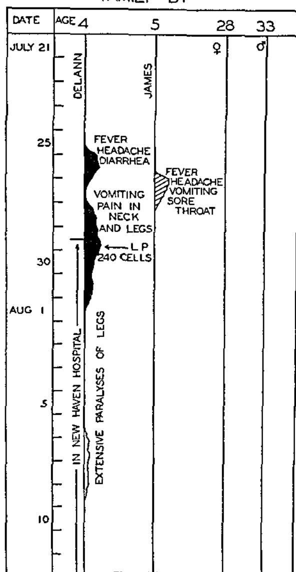

Fig 10—Diagram of a family with poliomyelitis Vertical lines indicate the family members their ages appear at the top Both children became ill at about the same time eventually one became paralyzed The presence of paralysis aids in the clinical diagnosis but it does not aid in determining which of the two children will excrete the most virus in their stools

Recent tonsillectomy operations (within six months) tend to lower the resistance of children and render them more susceptible than normals to the more serious forms of the disease Contrary to earlier teachings multiple cases within families are common although usually not more than one case in a family becomes paralyzed at a given time (Fig 10) There is evidence to suggest however, that in certain families a high prevalence of the paralytic form of the disease has prevailed through several generations

Morbid Anatomy—Important lesions occur in the gray matter of the spinal cord but it is a mistake to think of this disease as existing wholly in that part of the body Classical lesions, which are associated with paralysis, are the result of the neuronotropic *tendencies of the virus They involve the* ganglion cells in the anterior horn of the spinal cord particularly in the cervical and lumbar regions These lesions pass through several stages but at their height and later, they are characterized by destruction of neurons neuronophagia and perivascular and interstitial round cell infiltration In the brain the lesions show a selectivity for the motor cortex (especially area 4), lesions are also found in the vestibular nuclei and cerebellar centers Rarely have lesions been found in the olfactory bulbs in human cases —an important negative finding because it was once thought that the virus invariably entered the human body via the olfactory tract

Incubation Period—This is about ten days but it may be variable ranging from as short as five to as long as thirty five days Average figures place it at twelve to thirteen *days for paralytic cases and nine to ten* days for abortive cases the difference is due no doubt to the fact that the prodromal symptoms in the former (paralytic) may be so slight as to escape notice

Symptoms—With most patients poliomyelitis is a mild illness of short duration But in a certain proportion of those infected the disease is severe and its most serious manifestation occurs—namely myelitis

In a mild *abortive case* the onset is sudden with fever malaise *headache vomiting* and perhaps sore throat—symptoms which may last from a few hours to a few days The child may be restless and somnolent by turns and irritable when aroused and handled Vomiting and headache are characteristic early symptoms Diarrhea is not particularly common (if purgatives have

family the reasons for this in order to allay undue anxiety As the clinical picture of *abortive poliomyelitis* is essentially nonspecific it is obvious that mistakes will be made but too often the story is that a child with an acute illness stays in bed for only a day or two and then returns to play where he perhaps sustains a fall which is again followed by fever and subsequently by paralysis It is important therefore to protect such a patient from trauma during this stage of the disease Any (non emergency) operative procedure particularly tonsillectomy should be postponed in both sick and well children during epidemic times

In the *early febrile* stage one may follow the same measures as are employed in any acute infection but in this disease in particular one should guard the patient from meddlesome therapy and prolong the period of bed rest beyond that which is ordinarily used Bed rest for a week or ten days is advised for abortive cases Preliminary purgation is not advised nor are any procedures which will subject the patient to unnecessary strain The practice of splinting the limbs or back in an abortive case in order to 'rest' these parts and thus prevent paralysis is to be condemned

If hospital facilities are available one must decide early in an epidemic whether to hospitalize all the abortive (potentially paralytic) as well as the paralytic cases Difference of opinion exists on this point The correct procedure depends on local facilities and circumstances As a rule it does not seem wise to attempt to hospitalize all *suspicious* cases during epidemics

Although no specific treatment is today recognized for acute poliomyelitis *convalescent serum* has been widely used and has been regarded (particularly in certain parts of this country) almost as a specific measure No clear cut statistical evidence has come to the author s attention which indicates that children treated with adult or convalescent serum in any stage of the disease do better than do patients who receive either no serum or horse serum of certain types This does not imply however that adult or convalescent serum should never be used

During the *stage of active myelitis* (in which fever is usually present) the most important aspect of therapy is rest—and careful nursing Patients with acute paralysis are treated best in a hospital but care should be exerted that the trip to the hospital be made with a minimum of exertion to the patient If hyperesthesia of the limbs is present the handling and bathing of the patient should be reduced to a minimum For severe pain and restlessness one may give aspirin grains x (0 6 Gm) two or three times a day codeine grain ¼ or ½ (0 015 or 0 03 Gm) or rarely morphine grain ⅙ (0 007 Gm)

Aspects of nursing care are similar to those of an acute infection The diet should be light and fluids freely given an ice bag may help in cases when headaches are severe Moist heat applied to the back and limbs (see under convalescent treatment) is also advised During the early stage of acute myelitis when weakness or paralyses are developing the patient may be allowed to assume in bed whatever position is most comfortable A board can be placed against the foot of the bed against which the soles of the feet may rest so that he can have something to push against in shifting his position

Frequent (daily) *lumbar punctures* have been recommended by some on the theory that the removal of spinal fluid relieves pressure from the neighborhood of the lesion of the cord The efficacy of this form of treatment has however never been proved and there would seem to be a traumatic risk in the procedure

The immediate application of splints in the *stage of early paralysis of limbs* is not advised Protection of the recently paralyzed limb (rather than fixation), and the application of moist heat in order to reduce muscle spasm are the objectives to be sought

Constipation often develops It should not be regarded with alarm although it may be difficult to overcome It usually does not persist for more than a week The use of strong purgatives is not advised

Cases with *bulbar paralysis* require special treatment Owing to difficulty in swallowing secretions accumulate in the pharynx which may interfere with respiration Treatment should consist in postural drainage with frequent shifting of the patient s position by swabbing the throat or (if there are facilities) by suction using an aspirator such as

count is apt to reveal a moderate leukocytosis (10 000 to 14 000) with lymphoid cells ranging from 30 to 55 per cent

Differential Diagnosis—Poliomyelitis is one of the few infectious forms of myelitis It should be considered whenever flaccid paralysis (particularly paralysis without sensory changes) occurs in the presence of fever and in the absence of traumatic or other types of injury to the cord

It can be confused with the summer encephalitides particularly the *equine encephalomyelitides* or *St Louis encephalitis* Serious paralyses of the limbs do not usually occur, however, *in these encephalitides Post-measles encephalitis mumps encephalitis meningo encephalitis* (of undetermined type) *lymphocytic choriomeningitis* and *infectious neuronitis* are conditions that may simulate poliomyelitis

Other conditions which have been confused are the *acute meningitides* (of various types) tuberculous meningitis and rheumatic fever In these conditions the diagnosis is apt to become apparent in the course of time More rarely *acute osteomyelitis trichinosis acute appendicitis* and *lead poisoning* are mistaken for poliomyelitis

Prognosis—During the acute stage predictions as to eventual outcome or effects are risky Extensive paralysis may develop unexpectedly and rapidly even in the absence of fever The height of the fever bears little relationship to the extent of paralysis which may ensue However the duration of fever may be significant for as fever and other signs of acute infection recede the danger of the onset or extension of paralysis lessens

It has been said that in a moderately severe epidemic anywhere up to 70 per cent of the cases are paralyzed but such statements mean little because they depend so much upon criteria of diagnosis In this country prior to 1917 all but a few of the reported cases were designated as paralytic whereas in some recent epidemics both here and in Canada less than 50 per cent were paralytic This ratio differs in different epidemics Furthermore there is apt to be confusion with regard to the diagnosis of non paralytic cases For this and other reasons physicians and health officers should join forces early in an epidemic in order to decide upon various common forms of criteria and action

The case mortality rate will also vary according to diagnostic criteria It may range from 1 to 4 per cent or higher By far the highest mortality occurs in bulbar cases Fifty per cent or more of such patients die

The extent to which patients may hope to recover from *paralysis* in poliomyelitis is also subject to many variables When all the anterior horn cells which control a given area are killed it becomes inevitable that complete loss of power occurs in that region When the cells are but partially damaged perhaps due to pressure or impaired blood supply more or less recovery may be expected There may be no recovery of a single afflicted muscle and there may be a remarkable amount of recovery in a widespread lesion Lovett divided the period subsequent to the acute illness into three stages which are useful in estimating the patient s future (1) the acute stage lasting from the onset of the disease to the complete disappearance of muscle tenderness Roughly this is a matter of several weeks and in some instances much longer (2) the *convalescent stage* from the end of the acute stage to the time of maximum recovery—a period usually placed at two years and (3) the *chronic stage* starting from the end of the convalescent stage and representing the period when residual paralysis is more or less permanent

Treatment—In the acute case the physician must be prepared to withstand strong pressure to do something definite and specific —but there is no specific therapy and no drug therapy known at present which destroys the virus or controls its spread within the body None of the sulfonamide compounds is known to be efficacious

Nevertheless one s responsibility with regard to both mild and severe cases is clear During epidemics all brief febrile illnesses (in which the cause of fever is otherwise unexplained) should be regarded with more suspicion than in ordinary times and such children should be placed under medical observation—because many patients with this disease are for a period of a few days in a stage of *potential paralysis* At the same time one should explain carefully to the

EPIDEMIC ENCEPHALITIS

(Encephalitis Lethargica Epidemic Neuraxitis Epidemic Stupor Type A Encephalitis [Japan], Economo s Disease)

Definition —Epidemic encephalitis is an epidemic infectious malady causing both diffuse degenerative and disseminated inflammatory changes in the central nervous system and its coverings characterized clinically by a marked diversity of symptoms in different cases and in successive stages of the same case partly because of variations in the intensity of the infection partly because of differences in localization of the scattered inflammatory foci It is unfortunate that the name *epidemic encephalitis* has been chosen to designate this disease because at least one other type of encephalitis the St Louis type also occurs epidemically

History —The disease is probably not new though it has become generally known to the medical profession since the pandemic broke out in the winter of 1916–1917 Economo carefully described the disease at that time and called it lethargic encephalitis The noma" in the early nineties of the last century the "sleeping sickness" and ophthalmoplegia that were observed during the influenza epidemic of 1712 may have been the same disease Even the last pandemic may have begun before 1916 because Cruchet in Bordeaux states that he observed cases as early as 1915 During 1917 an epidemic occurred in Australia, reported by Breinl as a "mysterious disease" Economo believed that it was epidemic encephalitis In 1918 encephalitis became prevalent in France Netter recognizing it as an "Encéphalite lethargique epidémique" and in the spring of the same year the disease was met with in epidemic form in 51 sanitary districts in England The first case to be reported in the United States was observed in New York City in September 1918 Shortly afterward the malady began to appear in and to be reported from various parts of the United States and Canada In the first Vienna epidemic (1916–1917) the prevailing type (as in the epidemic in France in 1918) was the somnolent-ophthalmoplegic though there were also examples of the Parkinson like the hyperkinetic and the psychotic syndromes In the English epidemic of the same year bulbar paralytic types were common (at first supposed to be botulism) as were also Parkinson like and catatonic types (hence the name epidemic stupor") In the epidemic in Germany in 1919 the choreiform type the Parkinson like type and the tabetiform type (with pupillary disturbances hypotonia, and areflexia) were described In the great epidemic that began in Italy in 1919–1920 and spread over Austria and Germany the hyperkinetic-myelitic forms (choreiform myoclonic) predominated In America a great variety of types has been encountered though the somnolent ophthalmoplegic were more abundant at first later on the cases characterized by Parkinson like and hyperkinetic syndromes were more frequently seen This large epidemic widespread throughout the world continued from 1915 to 1925 At present only sporadic cases are encountered

Epidemiology —Although it has been assumed that the nasopharynx is the portal of entry the manner in which the virus is transmitted is not known In favor of the idea of contact infection is the fact that incidence among physicians has been exceptionally high Though instances of house infection of conjugal infection or of spread from one person to close companions have been few some have been reported Thus epidemic outbursts have occurred in England in institutions for young females and several children born of parents suffering from the disease have been infected No age is exempt Incidence appears to be greatest however between ten and forty five years of age thus differing from poliomyelitis in which the majority of those affected are children under ten years of age and from the St Louis type of encephalitis in which most of the people affected were more than forty five years old About three males are attacked to two females Occupation appears to exert no special influence upon the incidence of the disease Epidemic encephalitis is commonest during the winter and spring months and in this respect is different from poliomyelitis and the St Louis type of encephalitis which occur most frequently in the summer

Etiology —The cause of epidemic encephalitis is not known but there are reasons to believe that the etiologic agent is a filtrable virus The idea that a streptococcus or that a neurotropic strain of herpes simplex virus is responsible is not substantiated by experimental facts The conflicting views regarding the etiology of the disease are well presented in a paper by Zinsser in the Archives of Pathology 6 271 1928

Morbid Anatomy —On macroscopic examination of the nervous system areas of hyperemia in the meninges may be seen the vessels on the surface of the brain are engorged and on section the vessels appear prominent especially in the basal ganglia midbrain and pons where minute hemorrhages are sometimes visible On microscopic examination two changes can be made out one degenerative the other inflammatory and infiltrative One or the other predominates according to the stage of the disease at the time of death The degenerative process manifests itself by the destruction and

those used in an operating room Atropine (grain 1/100) may be of value in reducing the amount of secretion If swallowing is impaired, fluid salt and nutriment should be administered either by clysis or intravenously or by proctoclysis The amount of fluid administered is dependent on the age size and general condition of the patient

When *respiratory failure* occurs it is not always easy to decide which part of the respiratory system is involved If paralysis of the respiratory center of the medulla occurs little can be done other than the administration of oxygen and carbon dioxide in a 95 per cent and 5 per cent mixture respectively

The *Drinker respirator* has been widely used in cases of paralysis due to weakness of the respiratory muscles This is often an emergency procedure and once the patient has been put in the respirator much time and money may be spent before he can be removed Every effort should be made on the part of physicians and nurses (as well as hospital mechanics) to acquaint themselves with the technical details and responsibilities in operating the respirator before it is actually used The directions by Wilson are recommended

Early Convalescence—Patients should have orthopedic supervision in this stage and the advice of specialists for there are many conflicting points of view and one cannot be dogmatic about the treatment of paralysis The introduction of Miss Kenny's principles is a forward step which has done much to disparage the rigid fixation of all paralyzed or weakened limbs in splints The application of moist heat to the limbs and body and the early re education of muscles are measures now superseding the older methods This does not mean that physicians or surgeons untrained in orthopedics should be consulted any the less or that untrained nurses or attendants should attempt to apply any aspects of the convalescent therapeutic regime

Prophylaxis—Inasmuch as the mode of spread is unknown it is difficult to devise rules for prevention There are no rigid directions Isolation of patients as usually practiced seems to be ineffective in controlling the spread of the disease In the early stages of an epidemic it is wise to seek the counsel of the local health officer immediately so that a *uniform* plan may be adopted in which all physicians may join There are a few simple principles to follow (1) to recall that abortive cases may be infectious as well as the paralytic cases (2) to discourage the eating of uncooked food to which flies or many other sources of contamination may have had ready access (3) to discourage swimming in filthy ponds or in areas either grossly polluted by sewage or crowded with children among whom there may be carriers (4) to put a ban on tonsillectomy operations and other minor operations which may be postponed during the epidemic period

Injections of antisera (convalescent or adult blood) as a form of passive immunization have been suggested but the practical difficulties are great and their general use is not recommended

sist In some cases marked mental deterioration occurs and may be mistaken for general paresis Manic and melancholic states have been observed and less often a condition simulating dementia praecox has been seen

Other Types —Many other types have been described including a poliomyelitic type with lower motor neuron paralyses a posterior root ganglion type with herpes and radicular neuralgias or anesthesias a tabetic type with ataxia and sluggish pupils an epilepto maniacal type a cataleptic type with statuesque attitudes and an amyostatic kinetic type in which there is seen apathy rigidity akinesis without paralysis great slowing of movements amimic facies and sometimes, tremor

Aberrant Forms and Formes Frustes —Very peculiar aberrant forms of the disease may occur which simulate some other malady often of some part of the body other than the nervous system Examples of such aberrant forms are the intestinal types (Massari) the dyspneic types (Economo) and the fulminant cases that terminate fatally after a few hours (*Encephalitis siderans*) In one case observed by Barker and Sprunt tetany developed as the result of a post encephalitic paroxysmal hyperpnea Abortive forms and *formes frustes* are undoubtedly very common during epidemic periods nuclear paralyses in the domain of the cerebral nerves radicular neuralgias deafness vertigo or trismus may be the only manifestations

Second Stage —In the second or pseudo psychoneurotic stage there are many subjective complaints—headache insomnia dizziness fatigability irritability and restlessness—often without demonstrable objective findings of organic nervous disease The symptoms may however persist for months or even for years after which the symptoms of the third stage may appear Occasionally the symptoms of the third stage follow almost immediately upon those of the first In children the second stage may be marked by alterations of character and oddities of behavior (Hohman)

Third Stage —In the third or chronic stage peculiar motor vegetative and psychic symptoms make their appearance The disturbances of motility are like those of the Parkinson syndrome with or without tremor Among the commoner vegetative disturbances are sialorrhea dacryorrhea and seborrhea On the mental side there may be intellectual and emotional torpor with marked slowing of thought

Diagnosis —When the disease is epidemic and typical cases are occurring, encephalitis should always be suspected in puzzling cases of fever somnolence or delirium Signs of meningeal irritation external or internal ophthalmoplegia neuralgias or paralyses in cerebral nerve domains or pathologic drowsiness associated with fever or leukocytosis should always excite suspicion On lumbar puncture the cerebrospinal fluid may be normal but often there is an increase in the amount of globulin a slight increase in the number of cells and an increased or normal amount of sugar changes that are strongly corroborative of encephalitis when the Wassermann reaction is negative Helpful in diagnosis are the acute onset of nervous symptoms with evidence of predominant involvement of the gray matter the paucity of massive paralyses in contrast with an abundance of disturbances of multilocular origin in unusual combinations the tendency to transitory pareses rather than to complete paralyses and the nonsystematic nature of the observable symptoms

Among the conditions to be differentiated from epidemic encephalitis are botulism nervous forms of influenza epidemic cerebrospinal meningitis tuberculous meningitis, uremia cerebral hemorrhage cerebral embolism cerebral thrombosis cerebrospinal lues brain tumor acute anterior poliomyelitis multiple neuritis multiple sclerosis St Louis type of encephalitis acute lymphocytic choriomeningitis and postinfection encephalitis

Prognosis.—The mortality varies in different epidemics It probably amounts to 20 or 30 per cent if the outspoken cases only are considered the death rate would doubtless be lower if atypical and rudimentary cases were to be included Of the patients who do not die a large number recover rapidly others remain more or less invalid for from six months to two years still others are permanently disabled because of the severe symptoms of the third stage

Treatment —In the acute stage rest in bed isolation protection from avoidable

the indistinct staining of nerve cells The inflammatory change appears as scattered patches of infiltration especially in the gray matter with accumulation of small and large mononuclear cells and plasma cells in the sheaths of the vessels and in the perivascular spaces The nervous tissues themselves show also patches of diffuse infiltration with the same type of cells There are signs of neuronophagia Proliferation of the glial elements is seen in the areas of inflammation which tend to be most abundant in the basal ganglia midbrain and pons In chronic relapsing cases lesions of different ages have been demonstrable at autopsy Certain workers are inclined to believe that there is a systemic infection prior to the involvement of the central nervous system but proof of this view remains to be obtained

Incubation —It is believed that the incubation period in most instances is four to fifteen days

Symptoms —The mode of onset has varied markedly not only in different epidemics but also among cases in the same epidemic and may be either sudden or gradual The first symptoms may be those of an acute respiratory infection with headache malaise and fever In the Vienna epidemic of 1916–1917 there was usually a forestage with symptoms of slight meningeal irritation before the somnolence and paralyses of the eye muscles appeared In the United States the onset in some cases was sudden with severe pains in the head fever and delirium in other cases it was more insidious with fever diplopia and slight mental confusion or with sensory disturbances and pareses in cerebral nerve domains In a few cases the disease has been ushered in by a stroke of apoplexy an epileptiform attack a sudden syncope or a severe vertigo

First Stage —The clinical picture of the fully developed disease varies greatly A large number and variety of symptoms may be met with in the most diverse combination and sequence Experience with many cases indicates that the manifestations may simulate those of almost every well known neurologic symptom complex thus making differential diagnosis sometimes very difficult Certain syndromes however are more common than others and merit especial mention

In the first stage we meet most often with either (1) a somnolent ophthalmoplegic syndrome, or (2) an irritative hyperkinetic syndrome either choreiform or myoclonic

Somnolent Ophthalmoplegic Type —A triad of symptoms—fever somnolence, and ophthalmoplegia—characterizes the lethargic type of encephalitis After a brief initial stage with fever and symptoms of meningeal irritation the patient becomes drowsy and exhibits paralyses of the eye muscles Sometimes there are other symptoms—general rigidity paralyses in the limbs or head symptoms of motor irritation and delirium or other mental disturbances The fever may be slight or severe many afebrile cases have been noted

Hyperkinetic Types —In the hyperkinetic type following an initial stage of fever and excitement severe symptoms of motor irritation appear in the form either of choreiform (or choreo athetotic) movements or of myoclonic contractions In the choreiform variety there are involuntary and irregular movements of the automatic associated type these may be general unilateral or local in distribution and may vary much in intensity Occasionally the movements of an extremity are slow and rhythmical, recurring regularly eighteen or twenty times per minute (bradykinetic oscillation of Marie and Levy) The choreiform types are believed to be caused by lesions of the neostriatal system of neurons (Ramsay Hunt) In the myoclonic variety there is marked irregular twitching of muscles or parts of muscles probably due to irritative lesions in the spinal cord Bilateral twitching of the abdominal muscles may be an early sign of encephalitis (T F Reilly) Less common is a bilateral synchronous myoclonia during which the muscles of the trunk and of the proximal portions of the extremities contract fifty or sixty times per minute (Hamill) Persistent hiccup is common

Psychotic Types —Psychoses of the organic reaction type may dominate the clinical picture Mental grasp is impaired memory defects are evident orientation as to time place and persons is faulty and attention is disordered (Kirby) In the more acute forms delirium may alternate with pathologic drowsiness or stupor Emotional disturbances are common and tend to per

tis which is most prevalent in the winter and spring No age is exempt but the high est incidence is in individuals more than forty five years of age while Economo's en cephalitis usually attacks people ten to for ty five years old and poliomyelitis is princi pally a malady of children less than ten years of age In the St Louis 1933 epidemic the attack rate was considerably higher among inhabitants of the suburbs than among those in the city proper

Etiology —The disease is caused by a small filtrable virus possessing a diameter of 20 to 30 millimicra The agent has not been cultivated in a lifeless medium but has been propagated in one containing viable susceptible cells Albino mice and rhesus monkeys are susceptible hosts the former is the one of choice for the demonstration of virus in suspected material and for the per formance of neutralization tests used in ar riving at a diagnosis

Incubation —It has been estimated that incubation periods range from four to twen ty-one days

Morbid Anatomy —Edema vascular con gestion and small hemorrhages are usually evident upon gross examination of the brain and cord Microscopic examination reveals an infiltration of the meninges with lympho cytes plasma cells large mononuclear ele ments and an occasional polymorphonuclear cell In the brain and cord are evidences of an acute inflammation *e g* vascular con gestion small hemorrhages cellular infiltra tion perivascular cuffing degeneration of nerve cells neuronophagia and proliferation of glial elements The focal accumulations of cells around the blood vessels are limited to the Virchow Robin spaces and for the most part consist of elements with the morpho logic characteristics of lymphocytes In many instances there are foci of mononu clear cells bearing no relation to blood ves sels these seem to consist of lymphocytes and glial elements (oligodendroglia and microglia)

Symptoms —The fact that the clinical picture varies tremendously can be ex plained upon the basis of differences in the severity of the infection and the localization of lesions in the brain and cord According to Hempelmann the cases may be placed in three large groups

Group I —Patients in this group exhibit an abrupt onset without prodromal symp-toms High fever nausea, vomiting head ache, vertigo nuchal rigidity, Kernig s sign lethargy, difficulty with speech, ataxia, men tal confusion and tremor of tongue, lips or hands are the most common signs and symp-toms All the patients are not lethargic par alyses are not common and when they do occur are usually of the spastic type in volvement of the eye muscles is extremely rare a state of affairs very different from that met with in lethargic encephalitis The abdominal reflexes are usually absent while the deep reflexes tend to be exaggerated in stead of diminished Constipation is com mon The pulse is usually proportional to the temperature but a bradycardia may occur

The spinal fluid may be under increased pressure is free from ordinary bacteria, con tains a normal amount of sugar an increased amount of globulin and an increased num ber of cells consisting chiefly of lymphocytes and other mononuclear elements The num ber of cells in the fluid tends to be higher than that encountered in epidemic encepha litis The white blood count may be normal or show a leukocytosis

As the patient s condition improves the temperature falls by lysis and in most in stances reaches the normal level within seven to ten days in a few cases however the fever persists for from four to six weeks

Group II —In this group of cases a stage of invasion lasting from one to four days and characterized by headache general ma laise abdominal pains chilly sensations fever generalized muscular pains sore throat and a mild conjunctivitis accom panied by photophobia precedes the picture of encephalitis which after its development is similar in all respects to that described for Group I

Group III —The third group consists of mild or abortive cases exhibiting only head ache and fever of undetermined cause which would be missed in the absence of an epi demic and incorrectly diagnosed without the aid of a lumbar puncture

Diagnosis —Epidemics of the St Louis type of encephalitis are distinguishable from those of Economo s (lethargic) encephalitis but frequently individual cases of the for mer malady cannot be differentiated from

optic acoustic and tactile stimuli, skilful nursing restriction to a liquid diet and tepid sponging are beneficial Repeated lumbar punctures or hypertonic solution of glucose given intravenously frequently relieve the headache and diminish drowsiness of the early stages, especially when the pressure of the cerebrospinal fluid is increased Water should be given freely by mouth or by continuous Murphy drip if the patient be difficult to arouse For the nocturnal restlessness the bromides or barbital in hot milk may be useful In the hyperkinetic states and in violent delirium sedatives such as *paraldehyde and Schlesinger s solution* are required In spite of claims to the contrary there is no evidence that any of the vaccines or sera used in the treatment of the disease are of value

After the acute stage is over care should be exercised to avoid relapses Convalescents should be closely watched and their activities directed meticulously for a long time A prolonged period of rest after the acute stage is over may do much to prevent the development of the much dreaded third stage

The therapeutic resources of the physician will be severely taxed in the management of patients suffering from the symptoms of the third stage of the disease For the asthenia general upbuilding measures are helpful some patients seem to be benefited by adrenal residue (5 to 10 minims after each meal) For tremor and for parkinsonian rigidity doses of increasing size of hyoscine hydrobromide ($\frac{1}{200}$ to $\frac{1}{60}$ grain) are valuable or tincture of stramonium may be tried Large doses of sodium cacodylate given intravenously every four or five days have been much lauded In Vienna intravenous injections of sodium iodide have been found to be beneficial To promote recovery from paralyses massage and galvanism may be employed For sialorrhea atropine or hyoscine may be given in full doses Patients with severe psychotic symptoms or exhibiting anomalies of behavior may have to be cared for temporarily or permanently in a closed institution

This chapter was originally written by Dr L F Barker and the revised form of this edition is with certain exceptions identical with that prepared by him Dr Barker was kind enough to permit the use of his material in this manner

ST LOUIS TYPE OF ENCEPHALITIS

Definition—The St Louis type of encephalitis is a virus disease characterized by signs and symptoms referable to the central nervous system and its meninges but differing from epidemic encephalitis in certain important respects It may occur either epidemically or sporadically

History.—In the summer of 1933 in and around St Louis more than 1000 cases of encephalitis occurred The epidemic as a whole exhibited characteristics different from those observed in epidemics of Economo s disease or epidemic encephalitis Muckenfuss Armstrong and McCordock and Webster and Fite quickly demonstrated that the epidemic was caused by a filtrable virus previously unrecognized Soon it was also realized that the disease had occurred in the United States prior to 1933 particularly in Paris Illinois Furthermore it has been shown that the malady is now endemic in America cases having been reported each year since 1933

For many years Japanese workers have been aware of an epidemic summer encephalitis different from Economo s disease or epidemic encephalitis (Type A) and have designated it as Type B encephalitis In fact up to 1929 13 epidemics of the malady had been recorded *This encephalitis is immunologically different from the St Louis type*

Epidemiology—The mode of spread is not known The malady occurs most frequently during the summer months in this respect it differs from Economo s encephali

injections of emulsions of fresh normal rabbit brain, have produced in monkeys a perivascular demyelination manifested clinically by ataxia and paralyses

Incubation —In view of the indecision regarding the etiology of the disease it may seem inappropriate to speak of an incubation period Regardless of the cause of the encephalitis one cannot deny that there is a definite relation between it and the primary infections In any event there is a comparative constancy of incubation—that is of the period which elapses between the onset of the primary disease and the occurrence of the complicating encephalitis In the case of postvaccinal encephalitis the incubation period in most instances lies between the ninth and thirteenth days the most favored day being the eleventh In the case of antirabic vaccination the encephalitis or myelitis usually comes during the second half of the Pasteur treatment or after it has been completed In the case of measles the incubation period is not very constant but as a general rule the encephalitis follows the appearance of the rash at variable intervals—usually it comes after the defervescence and at times the patient may have fully recovered from the measles

Morbid Anatomy —Pathologic changes are found in both the white and gray matter of the brain and cord and are characterized by a minimal involvement of nerve cells and a perivascular infiltration or accumulation of cells accompanied by a destruction of myelin The perivascular collections of cells are not limited to the Virchow Robin spaces and consist largely of altered glial elements undergoing proliferation many of which become phagocytic and take up large amounts of fat and degenerated myelin This pathologic picture is decidedly unlike that seen in the encephalitides caused by viruses on the other hand in many respects it is similar to that seen in acute multiple sclerosis and allied conditions

Symptoms —There are two main types of the disease the encephalitic and the myelitic the former is more common in postvaccinal encephalitis the latter is seen most frequently during antirabic vaccination while both types occur with almost equal frequency after smallpox Under such conditions it is to be expected that the clinical picture will vary and that the form it takes will depend on whether the brain or cord is predominantly involved

The onset of the disease if not abrupt is rarely insidious and is manifested in the encephalitic cases by pyrexia headache vomiting and drowsiness—cardinal symptoms constantly present in severe, and rarely absent in mild cases they may be the only symptoms present even in fatal cases' Photophobia irritability, delirium general or local convulsions, trismus, strabismus incontinence of urine, extensive paralyses (spastic at first and then flaccid) or transient weakness of muscles incoordination and ataxia are symptoms that may occur Kernig's sign may be present the deep and superficial reflexes are variable In the myelitic cases symptoms caused by mild or severe involvement of the cord such as paralyses anesthesias paresthesias and disturbances of sphincter control are observed

The spinal fluid may be under increased pressure is sterile and may contain an increased number of cells which are usually mononuclear elements the amount of sugar is within normal limits

Diagnosis —The clinical picture of postinfection encephalitis is at times not unlike that caused by certain known viruses for example, the St Louis encephalitic virus Consequently, it is important to remember that all cases of encephalitis occurring in the wake of infectious diseases are not necessarily postinfection encephalitis In certain instances they undoubtedly represent other types for example some cases of encephalitis following antirabic vaccination are in reality rabies and some that occur after measles are of the hemorrhagic rather than the demyelinating type Often it is difficult and at times impossible by means of clinical observations alone to differentiate postinfection encephalitis from the other types In view of this fact a history of an encephalitis during convalescence from a virus malady usually results in a diagnosis of postinfection encephalitis As a rule such a diagnosis is correct but not always At present a definite diagnosis of postinfection encephalitis can be arrived at only by means of a careful examination of the brain and cord which should show a characteristic perivascular demyelination

those of the latter by means of clinical or pathologic observations alone Neutralization and complement fixation tests aid in arriving at a correct diagnosis

Prognosis—About 20 per cent of the patients die the mortality rate is much higher in old people than it is among the young Those who recover do so quickly as a rule and are not usually bothered by troublesome or disastrous sequelae

Treatment—Treatment is symptomatic

POSTINFECTION ENCEPHALITIS

(Acute Disseminated Encephalitis Acute Perivascular Myelinoclasis Postvaccinal Encephalitis Postmeasles Encephalitis)

Definition—Postinfection encephalitis is an acute malady of the central nervous system characterized by perivascular demyelination exhibiting itself as a rule in patients who are convalescing from infectious diseases particularly those caused by viruses or in those who are being vaccinated against virus maladies such as smallpox or rabies In certain instances the disease manifests itself in the absence of a history of preceding infection

History.—For a long time it has been known that an involvement of the central nervous system may complicate the picture of smallpox and measles In 1874 Westphal recorded descriptions of pathologic changes observed in the cords of patients who had died with nervous manifestations developing during an attack of smallpox and in 1886 Barlow and Penrose gave an account of a similar case that arose during the course of measles Soon after the initiation of vaccination against rabies it was realized that an occasional individual receiving the injections met with paralytic accidents which at times resulted in death In 1907 Comby described a case with involvement of the central nervous system as a complication of jennerian prophylaxis this observation was followed by a similar one made by Turnbull in 1912 Although isolated cases of the nature just mentioned had been described from time to time it was not until the outbreak of postvaccinal encephalitis in Holland England, and other countries in 1922 that attention was focused on them As the result of extended clinical pathologic, and experimental observations the tendency at present is to consider this type of nervous accident following in the wake of acute infections as a clinical entity

Epidemiology—The disease has been shown to occur during the course of and after vaccination against rabies and smallpox and during or after an attack of smallpox measles German measles varicella or influenza a few cases have been reported in which no history of a preceding infection was obtained The incidence varies from year to year being lower now after jennerian prophylaxis than it was in 1922–1925 It is not distributed uniformly throughout the population of a country nor are the inhabitants of all countries equally affected No age is exempt the malady occurs however more frequently in children than in infants and adults There is no evidence that the disease is contagious

Etiology—The cause of postinfection encephalitis is not known nor has the malady been transmitted from man to experimental animals The three most prevalent ideas regarding the etiology are (1) the viruses that cause the primary disease *e g* smallpox measles etc also give rise to the complicating encephalitis (2) a latent neurotropic virus is activated by the primary disease processes (3) inasmuch as the encephalitis occurs during convalescence from some infectious malady certain workers have suggested that it is an expression of allergic phenomena There is no convincing evidence that any of these ideas is correct Moreover it seems unlikely that the direct action of a virus is the cause of the disease because no virus is known to produce a perivascular demyelination similar to that seen in this disease Furthermore Rivers and his co workers by means of repeated intramuscular

The final link in the chain of epidemiologic circumstances to be accounted for is the mechanism whereby the virus survives from one season to the next Recent experimental work of Syverton and Berry suggests an explanation for this They showed that the tick *Dermacentor andersoni* could be infected by feeding on an infected animal This insect harbored the virus throughout its life and could pass it on to a succeeding generation through the ova

Prevention of the Disease in Horses.—Shahan and Giltner showed that a vaccine could be prepared by treating an emulsion of infective horse brain with formalin Although some evidence of protection was obtained with this preparation the results were not entirely satisfactory In 1935 Higbie and Howitt showed that the developing chick embyro could be infected with this virus In 1938 Beard Finkelstein Sealy and Wyckoff prepared a vaccine by formalinizing a suspension of infected chick embryo tissue Such tissues were found to contain a much higher content of virus than infective horse brain This material has been widely used during the past two years Vaccination of horses and mules is achieved by subcutaneous injection at weekly intervals of two doses of 10 cc each of the vaccine of triturated chick embryo tissue treated with 0 4 per cent formalin Experimental and field studies have shown that this method is very effective Practical sanitary measures should of course be employed such as screening stables and removing horses and mules from pastures after dark

The Disease in Man—Meyer in 1932 described three cases of encephalitis in individuals having contact with sick horses which he suspected might be due to the virus of the equine disease No proof for this suspicion was obtained however by biologic test

During the summer of 1938 an epidemic of the eastern variety of the disease occurred among horses in southeastern Massachusetts During this time and in the same area an unexpected number of human cases of encephalitis occurred These were proved by Fothergill Dingle Farber and Connerley and by Webster and Wright to be caused by the equine virus by isolating the infectious agent from the brain tissue of fatal cases

There were about 40 human cases in this outbreak with a mortality of 65 per cent The majority of cases occurred in young children 70 per cent of them under ten years of age During the summer of 1941 more than 3000 cases occurred in the north central states

The onset of the disease was usually sudden particularly in young children The temperature rose rapidly to 103° F to 105° F and generally remained at a high level during the course of the disease In some cases the disease was ushered in by a convulsion Repeated convulsions occurred during the course of the illness in many patients Deep coma occurred rapidly and persisted throughout the acute stage of the illness Nuchal rigidity, stiffness of the back and positive Kernig s sign were usually present Many of the younger patients developed a peculiar edema about the face and upper extremities In some of the older patients the onset was more gradual

Certain of the laboratory findings were of importance particularly during the first few days of illness A leukocytosis was always present The cerebrospinal fluid was under increased pressure and contained an increased amount of protein and a normal content of sugar The cell count varied from 200 to 2000 per cu mm Of considerable importance was the fact that from 60 to 90 per cent of the cells were polymorphonuclear leukocytes

In fatal cases death occurred at variable times during the course of the disease most commonly during the first few days In the few patients who recovered the acute phase of the illness terminated by lysis six to ten days after the onset The majority of the patients who survived were left with severe mental and physical damage

It must be emphasized that a diagnosis of encephalitis in man due to the virus of equine encephalomyelitis cannot be made on the basis of the clinical findings It may be confused with other types of acute infectious encephalitis such as polioencephalitis and St Louis encephalitis An increase in the incidence of encephalitis in man in an area where an epidemic of the disease in horses and mules is in progress should lead one strongly to suspect the equine type of the disease Virus was not isolated from any of

Prognosis—Ten to 50 per cent of the patients die the mortality rate is much higher in postvaccinal encephalitis (50 per cent) than it is in postmeasles encephalitis (10 per cent), the rate also varies from year to year in the same type being considerably lower now in postvaccinal encephalitis than it was in 1922–1925 The patients that recover usually do so completely, sequelae occasionally occur, and it seems that they are more frequent in cases developing after measles than in those following jennerian prophylaxis

Treatment—The treatment is symptomatic Headache may be relieved by repeated lumbar punctures and the intravenous administration of hypertonic glucose solution Definite evidence is lacking, in spite of claims to the contrary that convalescent measles serum etc are of therapeutic value

EQUINE ENCEPHALOMYELITIS

The Disease in Horses—This disease has undoubtedly been present among horses and mules in this country for many years having been diagnosed as botulism forage poisoning and so on In 1931 it was proved to be caused by a filtrable virus by Meyer Haring and Howitt during the course of their studies of an epidemic in the San Joaquin Valley in California Since then our knowledge of its extent epidemiology transmission prevention and so on has accumulated rapidly

In 1933 an epidemic occurred along the seacoast of Virginia and New Jersey which was shown by Ten Broeck and Merrill to be due to a virus immunologically distinct from that causing the disease in the West. The eastern disease moreover is more severe than the western, with a considerably higher mortality rate (about 90 per cent as compared to 25 to 30 per cent) The two diseases are referred to as the eastern and western types of equine encephalomyelitis The geographic distribution of each type appears to be strictly limited by the Appalachian Mountains

The first important clue to the mechanism of spread of epidemics was provided by Kelser's classic experiments in which he demonstrated that the virus could be transmitted by the mosquito *Aedes aegypti* Subsequently Kelser as well as other investigators has shown that other mosquitoes including *A sollicitans A cantator A vexans A taeniorhynchus A dorsalis A nigromaculis* and *A albopictus* may transmit the virus It is of interest that the *Anopheles* mosquitoes fail to transmit the virus Recent experiments have demonstrated transmission of the virus by *Culex tarsalis* The mosquito transmission of the virus adequately accounts for the spread of the disease in a particular area however it does not explain the sudden appearance of the malady in widely separated areas

Giltner and Shahan showed that pigeons were susceptible to infection following intracerebral inoculation of the virus and suggested that birds may play a role in the epizootiology of the disease Other investigators demonstrated that additional species of birds were susceptible During the course of the 1938 epidemic in Massachusetts Tyzzer Sellards and Bennett isolated the virus from pheasants dying in their natural state and Fothergill and Dingle isolated the virus from a pigeon under similar circumstances These findings clearly implicate birds in the epidemiology of the disease and explain its spread to widely separated areas Indeed it appears likely that the malady is primarily a disease of birds and that man and horses are accidental secondary hosts

rather generally throughout the United States Many thousands of cases are known to have occurred in Scandinavia and Finland within the past few years

In all countries where the disease has been observed there is a very definite seasonal occurrence it being met with almost exclusively during the warm months Figures from different sources show a rather wide variation in the age incidence of the disease but it seems probable than 50 per cent or slightly more of all cases are in children under fifteen years and 80 per cent under thirty The two sexes appear equally susceptible

Many careful studies of epidemics have failed to produce any evidence that contagion is transmitted by water food or insects On the other hand abundant data have accumulated which seem to indicate conclusively that the virus is spread by contact infection The incubation time is quite definitely established as from two to four days We have no accurate knowledge of possible immunity but no case of reinfection has been recorded

Etiology and Pathology —Exhaustive etiologic studies have failed to determine the exact nature of the disease There is some evidence however that the infection is due to filtrable virus presumably present in the nasopharyngeal secretions Since no post mortem examination has ever been made in a case of this disease we have no knowledge of its pathology Presumably the essential lesions of the disease are in the diaphragmatic pleura but their nature can only be a matter of conjecture Many patients have undergone a laparotomy with the mistaken diagnosis of an acute abdominal emergency but in no instance has any abnormality been observed in any of the abdominal organs or peritoneum

Symptoms —Prodromata are rarely present The onset is abrupt and often alarming because of the intensity of the symptoms and attending collapse This is especially true in children The earliest symptom is pain and throughout the course of the disease is its chief manifestation The seat of the pain is invariably at the level of the attachment of the diaphragm most commonly high in the epigastrium but often on one or both sides of the lower thorax anteriorly It may shift to some degree from day to day Its character varies considerably from a dull pressure or distress to the most acute type of paroxysmal seizure Pain is particularly associated with the respiratory function and is intensified by sneezing coughing exercise laughing and deep breathing Relief from the pain is naturally sought in a protective splinting of the lower thorax which can usually be accomplished by some fixed position and shallow breathing If able to move about the patient walks with the body bent toward the affected side and held in a fixed position while the gait is slow and painful A moderate degree of tenderness can often be made out over the painful areas and there is nearly always marked sensitiveness to deep pressure in the upper epigastrium The patient may also suffer from localized pain over small areas with cutaneous hyperesthesia in other parts of the body such as the lower abdomen lumbar region and over the shoulders back and sides of the neck

Fever invariably accompanies the pain and within a few hours may reach a maximum of 104° or even 105° F dropping to normal at the end of twenty four to forty eight hours or in mild cases still more promptly With any recrudescence of symptoms the temperature again rises and in cases running a severe course a continuous irregular fever sometimes persists for ten or more days The pulse rate at onset may be moderately elevated (90–100) Because of the pain the depth and rate of respiration are minimized In rare cases with great respiratory embarrassment a light degree of cyanosis has been noted Frontal headache is a frequent and important symptom but very variable in its intensity and of short duration Pain in the back and legs is rather common in children but rare in adults Chills in some form are present in the early stages in 50 per cent of cases Prostration may be extreme during the height of the pain but the attack is of such short duration that with relief of pain the rebound is surprising A particularly distinctive feature of epidemic pleurodynia is the marked tendency to recurrent attacks at intervals of one or two days (in our series 63 per cent)

Gastro intestinal symptoms play but a small role in adults but a prominent one in

the Massachusetts cases by inoculation of animals with blood or cerebrospinal fluid

A diagnosis can eventually be established in the majority of cases by certain biologic tests The most important of these is the isolation of the virus from the brain tissue of acute fatal cases obtained at necropsy It is advisable to take small portions of brain tissue from various regions in the brain and brain stem The tissue is emulsified in physiologic salt solution and inoculated intracerebrally into white Swiss mice or guinea pigs If virus is recovered it can be identified by immunologic tests (protective tests in actively immunized animals or by serum neutralization tests) If it is impossible to inoculate animals immediately brain tissue can be preserved in the ice box in a mixture of 50 per cent neutral glycerin in buffered Tyrode solution It is very important to preserve such material in a buffered mixture since the virus is inactivated very rapidly by the developing cadaveric acidity Histologic examination is of course of great value in diagnosis

In cases with a prolonged illness and in convalescent patients a diagnosis may be made by neutralization tests with patients serum Neutralizing antibodies appear in seven to ten days after the onset of the illness

Treatment —There is no specific therapy for this disease Treatment is entirely symptomatic consisting of the administration of sedatives for the control of convulsions administration of fluids parenterally and food by gavage during the period of coma

Prevention of the disease in man if an epidemic occurs should consist largely of sanitary measures Houses and particularly sleeping quarters should be screened against mosquitoes and children should not be allowed outside after sundown A vaccine similar to that for horses could be developed for use in man However the infrequency of the disease in the latter does not justify large scale vaccination The vaccination of laboratory personnel is indicated since Fothergill Holden and Wyckoff have reported a fatal case resulting from accidental infection in a laboratory

EPIDEMIC PLEURODYNIA

(*Bornholm Disease Myalgia Epidemica Devil s Grip Epidemic Transient Diaphragmatic Spasm Epidemic Diaphragmatic Pleurodynia*)

Definition —Epidemic pleurodynia is an acute infectious and highly contagious disease which occurs largely in epidemic form and is characterized by pyrexia headache and very severe paroxysmal pain in the region of the attachment of the diaphragm The attack is of brief duration but tends to one or more relapses

History —The disease was first observed in Iceland by Finsen in 1856 and again in 1863 but his account of these observations was not published until 1874 He recognized the epidemic nature of the disease and first used the designation pleurodynia

In 1888 Dabney recorded an Epidemic resembling Dengue in Virginia which was the first observation of pleurodynia to be made in America Reilly in 1889 and 1921 published accounts of small groups of cases under the designation of intercostal neuritis and unusual pain syndrome which were undoubtedly examples of the same disease

Incidence —The disease has a very wide geographic distribution and there is increasing evidence that it occurs in epidemics

THE RICKETTSIAL DISEASES

INTRODUCTION

The rickettsial diseases of man are world wide in distribution and in general may be defined as self limited specific diseases transmitted by arthropods and characterized by continued fever a rash and a positive Weil Felix reaction The causative micro-organisms —*Rickettsiae*—may be regarded as pathogenic representatives of minute bacterium like micro-organisms widely distributed among arachnids (ticks mites and spiders) and hexapods (insects) including many non blood sucking species The pathogenic rickettsiae exhibit numerous differences but all are gram negative stain feebly with aniline dyes and behave as obligate intracellular parasites in arthropods and in susceptible animals Three groups of human rickettsial diseases of man are now well established the typhus louse and flea vector group the Rocky Mountain spotted fever or tick vector group and the tsutsugamushi or mite (*Trombicula*) vector group In general the distinctive lesions of these diseases are found in relation to small blood vessels chiefly of the skin and central nervous system but also in the genitalia and other organs Trench fever is usually grouped with the rickettsial diseases because it is transmitted by the body louse The clinical course is unlike those of the three groups enumerated and the causative micro-organism is much more bacterium like than the others and does not invade the cells of the louse The Weil Felix reaction is negative in Trench fever

Further difficulty in constructing a categorical characterization of rickettsial diseases is presented by the recently recognized (1937) Q disease of Australia and subsequently discovered in this country in Montana and now known to be fairly widely distributed Q fever first known in Montana as Nine Mile fever is not accompanied by a rash it is self limited does not give a Weil Felix reaction and the important lesion in man is a pneumonitis The pathology in guinea pigs is also unlike that of other rickettsial diseases because of the presence of exudative and suppurative processes and minute proliferative lesions widespread in many organs The cause is a rickettsia like micro-organism transmitted by several species of ticks This organism *Rickettsia burneti* (or *Rickettsia diaporia*) has forms which unlike other rickettsiae pass through Berkfeld N filters In infected animals and in tissue cultures the organism grows both intracellularly and extracellularly There is also evidence that Q fever may be transmitted from man to man without the agency of ticks

There is but one proved rickettsial disease of animals—heartwater disease of cattle sheep and goats The organism *Rickettsia ruminantium* is tick transmitted In animals it is found in endothelial cells of blood vessels particularly in brain and kidneys The rickettsiae persist in endothelial cells after recovery of the animal

The Typhus Group—Two types are generally recognized one the classic epidemic European type the other the murine type so called because of its natural reservoir in rats Murine typhus is endemic throughout the world it is transmitted from rat to man by fleas

The Rocky Mountain Spotted Fever Group—No distinction should be made between the disease as it occurs in the South and East of the United States and that of the northwestern states The group includes the tick transmitted so-called *Sao Paulo typhus of Brazil* and other South American countries the *fièvre boutonneuse* of the Mediterranean countries *South African tick bite fever* and *Kenya fever*

Fievre boutonneuse and South African tick bite fever are characterized in this group by local sores (at the site of feeding of the tick) and regional adenitis

In the tsutsugamushi disease group are included the classic *tsutsugamushi disease of Japan rural typhus of Malaya* and the *mite fever of Sumatra* In Japan transmission is by larvae of *Trombicula akamushi* in Malaya and Sumatra also by the larvae of *Trombicula deliensis* and *T schuffneri*

The rickettsiae responsible for these three groups can be distinguished by their morphology and behavior in animals and tissue cultures The rickettsia of the Rocky Mountain spotted fever group *Dermacentroxenus rickettsi* has the unique property of invading nuclei of cells of the tick of susceptible animals and in tissue cultures

children In the latter group nausea and vomiting are very frequently initial symptoms while severe diarrhea with distention may be more striking than the pain Mild sore throat or slight conjunctivitis occasionally occurs Herpes labialis, hiccup and epistaxis are rare A localized pleural friction rub is very rarely heard during the early stages of the disease but no signs of actual pulmonary disease have ever been noted X ray examinations of the chest in the hands of many observers have failed to show any significant abnormalities

Blood cultures have been uniformly negative Bacteriologic examinations of the nasopharyngeal secretions as well as inoculation experiments on animals have yielded negative results The course of the leukocytic count is extremely irregular showing a variation from 3000 to 21,000 In the majority of cases, it is within normal limits A moderate eosinophilia (5 to 13 per cent) is frequently seen during convalescence and particularly in those cases with complicating pleuritis The urine shows only the characteristics common to any febrile condition

Complications —The complications are rather frequent though seldom serious *Fibrinous pleuritis* is the most common occurring in more than 50 per cent in some epidemics Localized friction may rarely be heard during the first day or two but complicating pleuritis does not appear until the end of the first week or even later The friction sound is commonly very loud heard over an extensive area occasionally bilateral, and may persist for weeks The patient can usually feel the rub but is without pain Fluid never develops and the fever disappears after the first two or three days *Fibrinous pericarditis* is a less frequent complication and apparently quite as innocuous *Orchitis* is common in some epidemics *Bronchopneumonia otitis media, pyelitis sinusitis* and *catarrhal jaundice* are among the more unusual complications The principal effect of such complications is to prolong the convalescence as ultimate recovery is complete

Diagnosis —When the disease occurs in epidemic form the diagnosis is seldom difficult as the sudden appearance of the triad, fever, headache and diaphragmatic pain combines to form a picture which is unique The chief difficulty arises in cases with very marked abdominal pain, spasm and tenderness which always suggest the possibility of some local *surgical emergency* If to the above are added nausea vomiting, and distention, as so often happens in children, the picture is still more suggestive The white blood count does not always aid us as we may occasionally find a considerable leukocytosis in epidemic pleurodynia The tenderness in this condition is superficial with unmistakable hyperalgesia of the skin as contrasted with the marked sensitiveness to deep pressure when visceral involvement is present The clinical picture in *dengue* and pleurodynia may show a striking resemblance but the pain localized in the back and joints glandular enlargement and skin rash of the former are usually sufficient to differentiate them *Grippe and influenza* occur in the cold months and the unique type of pain in pleurodynia is never simulated in either

Prognosis —The danger to life is insignificant as among many thousands of cases only 13 deaths are recorded Except for a somewhat protracted convalescence in occasional cases recovery is prompt and complete

Treatment —The course of the disease is so brief that therapy does not play an important role The intensity of the pain indicates the early and liberal use of analgesics such as the salicylates and opiates A swathe to the lower thorax usually furnishes considerable relief from the pain as does the local application of heat Counterirritants at the seat of pain are contraindicated Absolute rest in bed should be enforced as the pain is more easily controlled thereby and the course of the disease probably shortened

TYPHUS FEVER

(*War Fever Ship Fever Jail Fever Prison Fever Camp Fever Hospital Fever Tabardillo Brill s Disease*)

Definition—Typhus fever is an acute infectious disease transmitted sporadically by the rat flea in epidemics by the body louse characterized clinically by sudden onset continuous high fever terminating by rapid lysis after about fourteen days a general macular eruption tending to become hemorrhagic over trunk and limbs but avoiding the face a delirium which may pass into a final coma and a tracheobronchitis often followed by bronchopneumonia Pathologically it is characterized by proliferative and thrombotic lesions of the blood vessels of the skin musculature and central nervous system Epidemiologically there are two types of typhus one of the classic European type exemplified by louse borne epidemics throughout the world the other the murine type with the natural reservoirs in rats and therefore endemic in every country Zinsser has presented evidence that sporadic typhus (Brill s disease) in the United States represents a recurrence of typhus previously experienced in Europe The murine type prevalent in the southern United States is transmitted to man by the flea *Xenopsylla cheopis* possibly also by ingestion of food recently soiled by the excreta of rats The typhus of Mexico (tabardillo), a louse borne epidemic disease is of the murine type Elsewhere in the world the murine type has not been reported in epidemic form

History and Distribution.—Since its recognition as a disease entity in the sixteenth century typhus has been known as one of the great epidemic diseases of the world It has been associated in history with a massing of persons in cities prisons ships and armies and fatal epidemics have attended most of the great wars

Regions which are known to be important centers for the origin of epidemics (European type) are Central Europe Russia Ireland Italy Spain Turkey Abyssinia and Northern China The establishment of epidemics requires a population contented with or forced by circumstances into a state of lousiness

Murine typhus is known to exist in Africa Chile China Greece Indo China Malaya Manchuria Peru the Philippines and the United States It can be the origin of epidemics because after transmission to man by the flea it is carried by the body louse

Endemic Typhus in the United States—Knowledge of murine typhus began with Maxcy s discovery in 1926 that typhus existed in the southern United States unassociated with lice Dyer Rumreich and Badger in 1931 discovered the virus in Baltimore rats and in the same year Mooser Castaneda and Zinsser found the virus of tabardillo in Mexican rats Maxcy predicted that the rat flea would prove to be the carrier to man and this was verified by Dyer and his associates Rodents other than the rat known to harbor the virus of murine typhus are mice domestic and wild squirrels gophers the opossum and the wood chuck

Endemic murine typhus is present in

Immunology—The three groups are distinct immunologically All are pathogenic for many mammals and all have animal reservoirs The rat is the important reservoir for murine typhus and man the reservoir for the European strain Many animals including all rodents, are susceptible to typhus and in some rodents as in rats and squirrels, the infection persists for many months Likewise, most mammals are susceptible to the Rocky Mountain spotted fever group, rodents undoubtedly are of greatest importance in maintaining the virus in nature throughout the world while many species of ticks act as vectors

The one proved Japanese reservoir of tsutsugamushi disease is a field mouse (*vole*) while both house rats and field rats are reservoirs for the Malayan and Sumatran diseases

Rickettsia prowazeki the cause of typhus is pathogenic for the louse in that it fills the epithelial cells of the stomach so completely as to destroy function It is not transmitted through the egg to succeeding generations of lice *Dermacentroxenus rickettsi* even though it invades all tissues of ticks apparently causes no ill effects and is transmitted to succeeding generations via ova and spermatozoa All stages of the tick larva nymph and adult are capable of transmitting *D rickettsi* *Rickettsia tsutsugamushi* (*R orientalis*) has not been studied adequately in its vectors the larvae of *Trombicula* The nymphs and adults of Trombicula feed only upon plants There is some evidence that the rickettsiae are transmitted hereditarily in *Trombicula* although the adult apparently does not contain the virus in infectious form

The pathology of typhus and the Rocky Mountain spotted fever groups has been extensively studied and the nature and distribution of vascular lesions leading to thrombosis and to infiltration and proliferation of cells about small blood vessels explain adequately the oustanding cutaneous and nervous manifestations of the diseases The meagre and inadequate studies of the pathology of tsutsugamushi disease point also to a vascular pathology including minute lesions in the central nervous system

Immunity to typhus and Rocky Mountain spotted fever is of long duration A second and even a third attack have been reported with both but only after lapses of many years According to Zinsser Brill's disease is a recrudescence of European typhus and not a re infection Immunity to tsutsugamushi disease is less complete Re infection is not uncommon but second attacks are usually mild

Prophylaxis—Laboratory attempts to confer passive immunity to the rickettsial diseases in animals have been only partially successful No antiserum satisfactory for the treatment of humans has been achieved No chemotherapeutic agent including sulfanilamide and related compounds has proved to be of value

The voluminous growths of rickettsiae now obtainable by modified tissue culture technics and in developing chick embryos afford some promise of securing more effective immune serums Suspensions of rickettsiae are now also available for the study of specific diagnostic procedures—agglutination and complement fixation reactions—which will probably soon supersede the enigmatic though useful Weil Felix agglutination tests with various OX strains of *Bacillus proteus*

Vaccines for protection against rickettsial diseases consist of chemically killed rickettsiae obtained by various methods Vaccines made from living attenuated viruses are dangerous because in the presence of vectors the virus may be taken up by them and give rise eventually to a fully virulent strain

Notable success in protection against Rocky Mountain spotted fever has been achieved through the use of vaccines made from the tissues of heavily infected ticks Cultures in developing chick embryos are now being employed Typhus vaccines prepared from developing chick embryo cultures from animal tissues and from modified tissue cultures are now under trial and give promise of success The huge armies engaged in the present world war are giving opportunity for the testing of the various types of vaccines

The development of knowledge of the rickettsial diseases since Ricketts began his study of Rocky Mountain spotted fever in 1906 forms a most commendable chapter in American Medicine Investigators in our

examination made by the writer in Warsaw in 1920 small lesions in surprising abundance were present in cerebrum cerebellum medulla and the only portion of the spinal cord examined routinely the upper portion of the cervical cord These lesions are chiefly in the form of small tubercle like lesions proliferative in character composed in large part of neuroglia cells and mononuclear cells of mesenchymal origin macrophages These lesions have been interpreted as being secondary to lesions of small blood vessels and capillaries which are identical in nature with those occurring in the skin The blood vessels of the pia and arachnoid are only occasionally and those of the choroid plexus very rarely, involved In addition to these proliferative lesions which correspond in size to the various dimensions of miliary tubercles there is a *perivascular infiltration* corresponding to that found in many forms of encephalitis The distinctive typhus lesion however is proliferative in character The number and wide distribution of the typhus lesions in the central nervous system may be considered the cause of the severe nervous symptoms which form so prominent a part of the disease

Typhus Fever in Laboratory Animals—In monkeys and guinea pigs typhus runs a definite course as in man The blood vessel lesions are similar and brain lesions are constant In rats the disease is less distinctive and the virus persists for longer periods European typhus produces only an afebrile infection in white rats while endemic or murine strains produce a febrile reaction

Intraperitoneal inoculation of male rats and guinea pigs with the virus of endemic or murine typhus produces a copious exudate abounding in rickettsiae in the tunica vaginalis The European epidemic strains produce in guinea pigs a transient exudate with rickettsiae present at the onset of fever

There is good evidence that strains producing the tunica reaction represent rat flea borne mild typhus and that strains which do not produce this reaction are of a more virulent man louse borne epidemic type Cross immunity between these various strains is complete and cross agglutination of their rickettsiae occurs Recent studies indicate that after louse-man passage the rat flea borne strains acquire characteristics of the European epidemic type On the whole we must conclude that all strains of typhus are identical The tunica reaction to typhus should be distinguished from the scrotal swelling in guinea pigs in Rocky Mountain spotted fever which is caused by thrombosis of blood vessels and occurs irrespective of the manner of inoculation

Symptoms—*Prodromal Stage.*—The period of incubation lasts from eight to twelve days It is probable however that it may be more or less than this because according to the dosage incubation in guinea pigs may vary from five to twenty one days The onset is abrupt although previous to this the patient may recall minor symptoms such as weakness malaise headache while actual elevation of temperature has been observed a few days prior to the true onset

Invasion—As a rule the invasion is abrupt and accompanied by chills or rigor followed by fever from which the patient usually dates his illness Vomiting may occur but is infrequent The appetite may be lost from the beginning but this symptom is not constant The prostration is such that the patient is glad to take to his bed Neuromuscular and back pains are common though less prominent than in influenza and smallpox The fever is high with pulse in proportion and subject to considerable variation from hour to hour The face is usually flushed facies alert or anxious mental condition excited and active delirium may have begun The pulse may be dicrotic the spleen palpable often tender There is no glandular enlargement lacrimation or coryza On the contrary there may be slight dryness of the throat and tongue

Stage of Eruption—Eruption appears on the third to the seventh day usually by the fifth day in the form of round or oval irregular pink erythematous macules which are nonpalpable disappear upon pressure and appear at the base of the neck chest back abdomen and extremities The individual macules are usually 2 to 5 mm in diameter In a few cases the macular eruption is complicated and partially obscured by a mottled erythema which spares the face and is usually most pronounced on the chest back and arms This erythema does not last more than three days and on disap

many southern states Cumming for the six years 1931 to 1936 inclusive has given the number of cases as 300 904 1922 1307 1105, 1662 respectively For the year 1937 the United States Public Health Reports give 2308 cases most of which were distributed as follows Georgia 1006 Alabama 460 Texas 422 Florida 114 South Carolina 81 North Carolina 65

The disease is most common in persons whose occupations bring them into rat infested premises and therefore is most frequent in the handlers of foodstuffs The disease is most common in the late summer and fall The freedom of the population from lice explains the absence of epidemics

Etiology and Transmission —Epidemic typhus is transmitted by the body louse whose fecundity and feeding habits readily explain the rapid passage of the disease from person to person under crowded unsanitary conditions That *Rickettsia prowazeki* is the causative agent of typhus is accepted as proved throughout the world

There is no evidence that typhus is conveyed by sputum or human excreta In the louse *Rickettsia prowazeki* does not invade the salivary glands Because it is discharged in great numbers in the excreta of the louse while feeding it is probable that infection of man takes place through fecal soiling of the punctures or by scratching The virus survives for a number of days in louse excreta (eleven days at room temperature) and it is therefore possible that infection may pass via this medium alone since it has been shown that the virus can enter through slight abrasions of the skin

Epidemic typhus is most prevalent in the winter and early spring and decreases rapidly with the coming of warm weather The increase of clothing with fewer changes in the winter time favors multiplication of lice while the crowding of persons in housing and sleeping quarters facilitates the transference of lice No person becomes heavily louse infected who bathes and changes his underclothing weekly

Endemic (murine) typhus may be carried from rat to rat by the flea *Xenopsylla cheopis* the rat louse *Polyplax spinulosa* and possibly the tropical rat mite *Liponyssus bacoti* From rat to man the probable vector is the rat flea Lice infected with typhus die in about eleven days the rat flea, however remaining alive and infectious for several months

Animals may be infected with murine typhus by feeding materials containing the virus The virus of murine typhus is present in the urine of infected rats and there is reason to believe that humans may be infected by the ingestion of food soiled with rat urine

In endemic typhus in the southeastern United States the peak of incidence occurs in the late summer and fall seasons which correspond to the period of greatest activities of rats and their fleas

Morbid Anatomy —The gross pathology of typhus is not distinctive Many patients die and show but little change at autopsy except the bronchopneumonia often responsible for or contributory to death The *spleen* may be slightly enlarged before the second week, in the third week its size is within normal range The *rash* is usually evident at the time of the autopsy because of its petechial character *Skin necroses* or *gangrene* are occasionally found and there may be symmetrical gangrene of the skin covering the extremities *Thrombi* are rarely found in the large blood vessels The *central nervous system* rarely shows gross changes occasionally there is noted a diffuse pinkish coloration of the cortex with or without minute arachnoidal hemorrhages suggesting the gross findings of encephalitis of whatever origin The pathology of typhus is distinctly microscopical *Proliferative lesions* of the small blood vessels arteries veins and precapillaries are found wherever the rash occurs and in the skeletal muscles The proliferative lesions are usually the site of mural thrombi and occluding thrombi often occur and are responsible for the necroses of the skin seen during life A distinctive perivascular infiltration occurs in the skin producing the so called *typhus nodules* of Frankel In doubtful cases excision of the skin is sometimes resorted to for purposes of microscopic diagnosis Perivascular infiltrations and somewhat similar nodular formation may be found in a few other organs notably the heart while in the *central nervous system* the lesions are perhaps more abundant than anywhere else in the body other than in the skin In every *postmortem*

been noted that in experimental animals the occasional deaths from typhus are those with unusually severe nervous lesions

Clinical Pathology —The *Weil Felix agglutination reaction* is quite constant For this purpose standard cultures of proteus bacillus must be employed Those designated as OX 19 are used and are distributed in laboratories throughout the world Suspensions of living cultures should be used and should be grown upon an agar medium prepared from fresh meat broth accurately adjusted to *p*H 7 4 The medium should be sterilized on three successive days at 100° C Only agar slants with water of condensation should be employed Only the macroscopic technic should be used Readings should be made after incubation at 37° C for two hours and an additional six hours at room temperature In typhus the agglutination reaction does not appear before the fourth day and the highest titer is reached just before or just after the fall in temperature The titer reaches 1 100 to 1 200 by the end of the first week and may at the end of the period of fever reach 1 5000 The initial titer obtained is of minor diagnostic value A rise of agglutination titer during the course of the disease is of great importance as a diagnostic aid

The cultures used for the tests should be constantly checked as the O variant of X 19 is unstable

The *blood* shows no striking changes the white count in uncomplicated cases rarely exceeds 12 000 Cases with marked leukocytosis are unfavorable The *urine* shows changes common to other fevers The *blood pressure* remains strikingly low throughout the disease

Endemic Typhus in the United States — Endemic typhus of murine origin throughout the world is similar in clinical and laboratory aspects to epidemic typhus although it is a much milder disease with a very low death rate

The incubation period is from six to fourteen days The duration of fever is the same as that of epidemic typhus—fourteen days—and terminates by rapid lysis Patients are usually afebrile by the sixteenth day The pulse usually does not exceed 100 The rash is like that of epidemic typhus but is less extensive and petechiae are less frequent Extensive skin necroses have not been reported The pathology in man and in guinea pigs is like that of European epidemic typhus

Complications and Sequelae —*Bronchitis* and *bronchopneumonia* are the outstanding complications of typhus and the chief cause of mortality among the Warsaw cases was bronchopneumonia The onset of pulmonary signs may be insidious or abrupt and it is obvious that various types of infection of the lungs occur chiefly streptococcus and pneumococcus The great irregularity of the heart with rapid and feeble pulse and sometimes evidence of dilatation may be taken as evidence of myocardial degeneration which is often demonstrable at autopsy On the other hand with recovery there are apparently no unfavorable after-effects in individuals who have exhibited marked cardiac signs *Infections of the parotid and submaxillary glands* are not infrequent complications of typhus and should be guarded against by careful cleansing of the mouth *Gastro-intestinal* complications are of minor importance and consist in vomiting and diarrhea The latter is common during the height of the disease The *delirium* and mental disturbance of typhus are to be regarded as a part of the disease rather than as complications *Otitis media* occurs as in other infectious diseases with some frequency *Thrombosis* of large arteries often causes serious complications Peripheral as well as abdominal vessels are affected In the Warsaw series there were cases of thrombosis of the mesenteric carotid pulmonary and splenic arteries Thrombosis of small cutaneous vessels results in the extraordinary necrosis and gangrene of the skin so commonly observed in typhus epidemics Previous impairment of circulation from pressure and cold is suspected as a predisposing cause as the necroses are particularly apt to occur over bony prominences such as the hips sacrum elbows and scapulae The resulting sloughs may involve the underlying subcutaneous tissue and muscles Symmetric gangrene of the extremities also has been frequently noted in typhus

Diagnosis —Prior to the appearance of the rash the signs and symptoms of typhus are so similar to many other *acute infectious*

pearing leaves the macular eruption more clearly evident Rarely large macules are *distinctly palpable The conjunctivae at this* stage of the eruption are markedly injected The tongue in severe cases is dry and per*haps fissured There is usually a cough* which by this time has become loose, and rales sibilant and sonorous are heard over *the lungs The eruption becomes more pro* fuse roughly in proportion to the severity of the disease and in severe cases the lesions *become almost confluent At first light* pink they become deeper pink to bright purplish red, and finally become brownish red in ap*pearance because of extravasation of blood* and on pressure remain a dull red In severe cases more striking purplish red petechiae *occur sometimes of considerable size* Mark

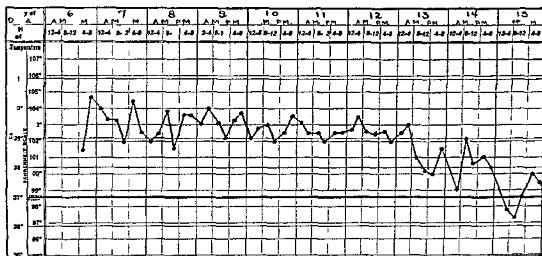

Fig 11—A typical temperature curve of uncomplicated typhus in a young patient who recovered

edly hemorrhagic rashes may be accompanied by hematuria hematemesis and melena and such cases are apt to be rapidly fatal The fever is usually at its height from the fifth to the tenth day More important however, than the fever, in prognosis is the severity of mental symptoms and complications The temperature remains high but somewhat irregular until the tenth or twelfth day when more marked remissions usually appear with a rapid decrease to normal on about the fourteenth day (Fig 11) The pulse rate is *more rapid than in* typhoid and a decrease may precede the fall in temperature The mental and nervous symptoms are *more striking* than in any other acute general febrile disease and in some cases there may be retraction of the head and other symptoms simulating cerebrospinal fever The cerebrospinal fluid however, shows but a slight increase in mononuclear cells and the fluid is not markedly turbid Palfrey attaches great prognostic importance to the mental and nervous symptoms of the patient during the tenth to twelfth days In some cases in spite of a fall of temperature the mental condition becomes worse changing from delirium to coma with carphologia muscular twitchings and incontinence of urine and feces In these cases the rash remains profuse and becomes increasingly hemorrhagic Such patients remain unconscious with increasing exhaustion and emaciation in spite of normal or almost normal temperature for a period of *a few days to a week and die usually with* terminal bronchopneumonia In favorable cases around the tenth or twelfth day a striking improvement occurs Although still delirious the patient becomes quieter, with an appearance of relaxation in spite of exhaustion The flush of the face disappears the pulse is less intense the rash less evident and the skin may be moist The fever becomes remittent and unless complications ensue the *temperature drops to normal* within a few days

The study of the Warsaw cases would *indicate that relatively* mild typhus infections may result fatally because of the severity of the complicating bronchopneumonia while on the other hand severe typhus results in death because of the extensive involvement of the central nervous system It has also

Prophylaxis—Prophylactic measures in general may be summed up as those directed against lousiness Persons attending patients should wear protective clothing preferably a one piece gown constructed with stocking footed trousers with no orifices except at the neck and wrists Close fitting rubber gloves should be worn over the wrists and the neck opening should be sprayed daily with an effective repellent, such as oil of cedarwood or a solution of naphthalene Nurses should wear in addition a head covering to confine the hair The gown should be inspected frequently while being worn and after each exposure should be deloused by heat naphthalene or chloro form Heat is preferable—a temperature of 55° C (131° F) for fifteen minutes is suf ficient Bacot recommends the melting point of stearin about 60° C, as an indi cator If steam is used the temperature should be kept at 65° C or above For bun dles of clothes two to three hours at 100° C is the minimum Bedding or clothing may be disinfected by immersion in hot water at 65° C for thirty minutes or by soaking without heat in 2.5 per cent Lysol for twenty minutes if dried without rinsing Crude flaked naphthalene in a reasonably air tight receptacle kills lice within ten or twelve hours As soon as typhus is suspected the patient should be freed from lice and nits and placed in a louse free environment His previous surroundings should be deloused and quarantined In times of typhus epid emics it is wise to take precautions to pre- vent carriage of lice into the wards by ambulance drivers and other attendants All blankets and clothing removed from the patient should be carried to a disinfecting chamber The delousing of the patient should be superintended by an intelligent and trustworthy person The patient should be clipped with especial reference to head axillae pubic and anal regions bathed thor oughly dried and then sprayed or rubbed with a light oil such as kerosene or liquid petrolatum The head should be generously soused with this oil and tied up in a cloth for twelve hours During epidemics segre gation and quarantine of contacts and im migrants from other typhus infected areas should be required for a period of sixteen days in addition to delousing procedures The methods employed by Strong in the Serbian epidemic were effective There is good evidence from many parts of the world of the value of prophylactic vaccination in times of epidemics The various forms of vaccine prepared from chemically killed sus- pensions of *Rickettsia prowazeki* all appear to be effective in reducing the severity and incidence of the disease

Treatment—There is no specific treat ment for typhus Treatment should be di rected toward supporting the patient and eliminating as far as possible the sources of exhaustion until spontaneous recovery can occur Continuous rest in bed and nursing are most essential An abundant diet of soft solids should be given according to appetite and digestion Liquids should be given fre quently and in abundance Every effort should be made to combat the dryness of the mouth and to keep the oral cavity clean it is advisable to apply a cleansing solution every few hours Where necessary in delirious or comatose patients nasal or esophageal tube feeding should be resorted to Bathing should be practiced as in typhoid The bowels should be kept open with enemas and retention of urine should be guarded against Headache should be treated with an ice bag Antipyretics are to be permitted only when the headache is out of proportion to the severity of the gen eral condition For the exhausting insomnia veronal or chloral and for the more violent delirium hyoscine hypodermically, with or without morphine should be given with the idea of conserving the strength of the pa tient The cough if exhausting should be treated by the usual cough mixtures with the addition of sedatives The onset of pneumonia requires additional efforts to ward diminishing the exhausting effects of restlessness excitement and cough Small hypodermic doses of morphine proved useful in Warsaw The possibility of skin necroses and gangrene should be kept in mind The employment of pads to avoid pressure from bed clothing and frequent changes of posi tion should be instituted upon the slightest indication of these complications There should be constant supervision of typhus patients in order to guard against accidents in delirium After recovery the effects of nervous and mental exhaustion may persist

diseases as to make a differential diagnosis impossible, although in the presence of an epidemic the diagnosis may be made upon suspicion The predominance of chill in typhus and of neuromuscular pains and coryza in other acute diseases is of assist ance *Malaria* and *relapsing fever* may be excluded by examination of the blood for the parasites *Pneumonia* may cause con fusion until characteristic pneumonic symp toms appear, such as accelerated respiration, rusty sputum, and the physical signs *Meningitis* should seldom be mistaken, as menin geal symptoms occur only late in typhus Lumbar puncture would eventually establish a diagnosis In *measles* the coryza and lacrimation give a possibility of early distinction *Smallpox* while it may simulate typhus in the first four days reveals itself later by the characteristic rash *Scarlet fever* is distinguished by the character of the rash and other signs in the throat and on the tongue *Typhoid fever* is so different from typhus in its mode of onset that the dif ferential diagnosis is usually not difficult when a clear history can be obtained Blood cultures and Widal reactions may be re sorted to In the absence of history and in a late stage of the disease there are some differences pointed out by Palfrey The typhus patient is more apt to be excited with active delirium and tense facies in con trast to the more stuporous mental condition and relaxed facies of typhoid The typhoid patient also lacks the injected conjunctivae and shows less flushing of the face The rash in typhus is more profuse than in typhoid and in the latter disease the rose spots are usually palpable and do not become hemor rhagic Skin excision may be resorted to The enlarged spleen persists in typhoid In recent years it has become necessary to dif ferentiate *encephalitis lethargica* in countries where it coexists with typhus The onset is usually gradual as contrasted with typhus the temperature lower rarely exceeding 102° F and the period of fever short There is no splenic enlargement and no eruption In the United States especially in the southeastern section, differential diagnosis between typhus and mild strains of spotted fever may present great difficulties The history of an insect bite or of the crushing of an insect by the patient may be of great importance since spotted fever is carried by ticks, and typhus by the rat flea and body louse (practically always the rat flea in the United States) Louse-borne typhus is most prevalent in the winter flea borne typhus in the late summer and fall and spotted fever in the spring and summer Spotted fever is more apt to produce symptoms in children than typhus and its occur rence is largely in rural districts, while typhus is primarily urban The distribution of the rash differs in the two diseases (see above and below)

The Weil Felix reaction is positive in both diseases Although there are some differ ences in the agglutination reactions to the three strains (OX 19 OX 2 and OXK) of *B proteus* employed they are not suf ficiently constant for the purposes of differ ential diagnosis In many instances it may be necessary to resort to animal inoculation rats and guinea pigs, and to make cross immunity tests

A specific complement fixation reaction for endemic typhus by use of an antigen prepared from rickettsiae grown in the yolk sac of developing chick embryos has been reported by Bengtson and Topping Con sult the chapter on Rocky Mountain spotted fever for a further discussion of the dif ferential diagnosis of typhus and spotted fever

Prognosis —The mortality of typhus in different epidemics has varied greatly 50 and even 70 per cent for one extreme down to approximately 5 per cent for the other In endemic typhus of the United States, according to Dyer, the mortality rate is less than 1 per cent and most of the deaths occur in patients above fifty years of age Factors such as ventilation lack of attend ance food and water and even of beds have undoubtedly contributed to the high mor tality of the worst epidemics There is a general feeling among the laity and phys icians that the educated classes have a higher mortality In childhood the disease is mild, in the second decade it is more severe but death rarely occurs in individuals under twenty years of age The mortality increases with the age The liability to a severe bron chopneumonia becomes greater and also persistent cerebral symptoms play a more important part

cajennense In the mountain states where rabbits constitute a reservoir of the virus the rabbit tick *Haemaphysalis leporis palustris* is the vector among these animals In South America, *Amblyomma cajennense* is the common vector but other ticks are in volved The list of proved and potential vectors of Rocky Mountain spotted fever includes ten species of ticks distributed in four genera

The late recognition of Rocky Mountain spotted fever in the East should not be re garded as evidence of its spread from the West There is reason to believe that the dis ease has existed in some Eastern states for an indefinite period Mild and severe infec tions both occur in all localities and there are no essential differences in the pathology of fatal cases from East and West

The total number of cases reported for the five years 1933 to 1937 inclusive was 2190 with 420 deaths of these 1435 cases and 273 deaths were from the Mountain and Pacific states with a death rate of 19 4 per cent

The mortality varies greatly but remains fairly constant in different localities In the Bitter Root Valley it is over 80 per cent for adults and about 37.5 per cent for children Regions of high mortality exist in other states When the disease was more prevalent in Idaho the mortality was less than 5 per cent now with fewer cases it has increased to above 25 per cent In Brazil the mortality rate is about 80 per cent

Etiology —*Dermacentroxenus rickettsi* the proved cause of the Rocky Mountain spotted fever group has a number of char acteristics which distinguish it from the rickettsiae of the typhus and tsutsugamushi groups in addition to immunological dif ferences Chief of these are its cyclic mor phology in ticks its hereditary transmission in ticks and its intranuclear growth in tick and mammalian tissues

Morbid Anatomy —The study of Rocky Mountain spotted fever has been greatly facilitated by the fact that the disease is exactly duplicated in laboratory animals (monkeys rabbits and guinea pigs) in re spect to its general course and the distribu tion and character of the lesions The pathology of the disease resembles in many respects that of typhus The distinctive gross lesions are those resulting from the thrombosis of blood vessels In the male there is frequently extensive hemorrhage and necrosis in the tissues of the scrotum There also may be necrosis of the skin of the ears face, fingers toes and vulva The spleen in man and animals is enlarged to several times the normal size it is firm and dark red Gross changes in the other organs of the body are essentially lacking The blood is dark red and clots slowly The right side of the heart is commonly dilated but the myocardium shows no change The lungs are normal unless there has been sec ondary pneumonia The gastro intestinal tract pancreas liver the adrenal glands and kidneys show no gross lesions In spite of the hemorrhagic lesions of the testes and ovaries the bladder prostate and uterus show no lesions In cases of long duration the marrow of the long bones becomes red because of resumption of activity The blood vessel lesions consist at first of a prolifera tive reaction of the endothelium followed by thrombosis either mural or occluding A considerable degree of perivascular infiltra tion occurs but the perivascular nodules so distinctive of typhus do not develop The parasite of the disease is found in endothe lial cells and also in smooth muscle cells of blood vessel walls Arteries veins and capil laries are affected Minute focal lesions of the central nervous system resembling those of typhus but accompanied by more con spicuous infarction of arterioles are common in cases which survive more than twelve days and therefore have been most often found in postmortems upon eastern cases Enlargement of the spleen is less marked and hemorrhagic lesions of the skin serous membranes and elsewhere are less common than with the western type

The *clinical laboratory findings* are not impressive The *urine* is that of any febrile disease In uncomplicated cases there is a slight leukocytosis There is an increase in the large mononuclear leukocytes exclusive of lymphocytes The *red cells* decrease in number as the disease progresses and may fall below 3 500 000 Eosinophils are de creased and may be entirely ab ent

The Weil Felix reaction is of some value in diagnosis All three types of *B proteus* employed (OX 19 OX 2 and OXK strains)

for some time and should be taken into account before the patient is permitted to resume normal activities

ROCKY MOUNTAIN SPOTTED FEVER

(Black Fever Blue Disease Tick Fever)

Definition—Rocky Mountain spotted fever is an acute specific infectious endangiitis, chiefly of the peripheral blood vessels transmitted by ticks and characterized by onset with chills, continued fever terminating in lysis severe pains in bones and muscles headache, and a macular eruption becoming petechial which appears first on wrists ankles and back and then over the whole surface of the body

History—The disease has probably existed in Idaho and Montana since the first settlement by white man and seems to have been known to the Indians before that time It was first described by Surgeon Major W W Wood in 1896 in a report to the Surgeon-General Maxcy of Idaho and McCullough, of Montana gave the earliest clinical descriptions of the disease Important laboratory and field investigations were made by Wilson and Chowning and Ricketts and his associates Ricketts established the transmission of the disease by the tick, and defined most of the problems which have resulted in our present knowledge of the disease and its causation

Distribution, Transmission and Incidence—The generalization may be made that diseases of the *Rocky Mountain* spotted fever group exist throughout the world wherever *Ixodidae* have opportunity to feed upon men Probably most of the rodents and other mammals which nurture the ticks are reservoirs of the rickettsiae In addition, the rickettsiae are transmitted hereditarily in the tick

In the United States the distribution of *Rocky Mountain spotted fever supports* the above generalization The distribution of the disease as known in 1920 included the states of Idaho Montana Utah, Wyoming Nevada Oregon Washington, Colorado California New Mexico, South Dakota and North Dakota The identification of the disease in the East by Badger Dyer and Rumreich in 1931 was followed by the rapid recognition of its prevalence in the Central and Eastern States Now, July 1942 the only states from which the disease has not been reported are Maine Michigan, Mississippi New Hampshire, Vermont and Wisconsin In the East the highest incidence is in Maryland Virginia and North Carolina

In the Rocky Mountain Pacific coast states the wood tick *Dermacentor andersoni* is responsible for transmission to man In the East and South the dog tick *Dermacentor variabilis* is the important carrier The brown dog tick *Rhipicephalus sanguineus* of the South and East, is probably also a carrier to man as laboratory experiments indicate and because it is the known transmitter of fievre boutonneuse

The seasonal incidence of spotted fever corresponds to the tick seasons of the locality concerned In the northwestern region *Dermacentor andersoni* appears in February and a few can be found during August and September They are most prevalent from the middle of March to the middle of June and hence spotted fever in that region occurs from March to July, with occasional cases later up to October

Dermacentor variabilis in the East appear in March and are most abundant from May to July though found as late as November and December Eastern spotted fever has been reported from March to December with the greatest incidence in June and July

Other ticks of the United States which may transmit the disease because they feed upon man are *Dermacentor occidentalis* *Amblyomma americanum* and *Amblyomma*

is due to stasis of blood in the subcutaneous vessels because of thrombosis In mild cases the rash does not become confluent and the petechiae, remaining small give a peculiar mottling which several Idaho physicians have compared to the markings of turkeys eggs Slight icterus may appear in the second week of the disease The rash begins to disappear with the subsidence of fever, but may long be indicated by the persistence of pigmented spots *Necrosis* of the skin of the scrotum prepuce fingers toes vulva lobes of the ear, and mucous membrane of the soft palate may occur in the third week *Desquamation* follows recovery but is slight except where the lesions have been most marked Minute cicatrices in the skin may persist for a long time after recovery

Nervous Symptoms—Restlessness and insomnia are very common through the disease and constitute its most distressing features Hyperesthesia may be severe Delirium is usual in severe cases during the height of the fever and coma usually precedes death by a few hours or a day Rarely convulsions muscular rigidity and opisthotonos occur Following recovery deafness visual disturbances slurring speech and mental confusion for a few weeks have been noted

Complications—Pneumonia is the one complication and is not frequent

Immunity—Recovery from Rocky Mountain spotted fever is accompanied by complete immunity for a long period of years According to Parker (1938) second infections have been reported eight or more years after the first in some instances ending fatally In guinea pigs recovering from feebly virulent strains does not protect fully from highly virulent strains Recovery from virulent strains does confer complete and lasting immunity in animals

A brief period of passive immunity may be conferred by the injection of blood from an immune animal

Active immunity can be produced by the injection of chemically killed rickettsiae obtained either from emulsions of the organs of infected ticks or from tissue cultures

The vaccine prepared from ticks by the United States Public Health Service which has been used since 1925 is of proved value in prophylaxis Its use has reduced the number of cases It protects completely against less virulent strains and greatly ameliorates the severity of the disease in regions of greatest virulence As the immunity reaches its height within a year, the vaccine should be used each spring in order to protect persons constantly exposed to the disease

Diagnosis—Theoretically the same diseases must be considered in the differential diagnosis of Rocky Mountain spotted fever as in typhus but practically the seasonal incidence and restricted distribution of the disease eliminate a number of possibilities *Cerebrospinal fever* and *measles* are the two diseases most liable to be temporarily mistaken for Rocky Mountain spotted fever In cases of doubt spinal puncture should be resorted to when there is a question of cerebrospinal fever as the rash may simulate that of Rocky Mountain spotted fever Usually the more severe nervous symptoms with early rigidity of the neck and character of the onset should serve to differentiate the two Measles at its height in children presents difficulty as the rash may resemble the early rash of spotted fever very closely The history of slower onset with coryza and lacrimation the presence of Koplik s spots the absence of severe muscular pains and the papular character and sequence of distribution of the rash are the most important differential data Typhoid fever with a pronounced rash may also have to be excluded The rash in typhoid fever however is more palpable and elevated than in Rocky Mountain spotted fever and is generally more restricted to the trunk A slower pulse rate lower fever diarrhea and positive blood cultures, or a positive Widal make final exclusion easy

Since Rocky Mountain spotted fever and endemic (murine) typhus co exist in at least twenty three states the problem of differential diagnosis often arises

Spotted fever is essentially a rural disease and exposure to ticks is important Most cases occur in the spring and early summer Endemic typhus is essentially urban it is a disease of late summer and autumn and occurs most often in persons frequenting rat infested premises and hence in those handling foodstuffs

The outstanding clin cal difference is in the evolution and distribution of the rash

may be agglutinated but most often the OX 19 strain is agglutinated in highest titer occasionally the OX 2 titer is higher and rarely the OXK strain gives the highest titer A titer of 1 320 is the lowest that can be considered diagnostic, but as in typhus a rising titer during the course of the dis ease is of greatest significance A test should be made as early as possible in the disease and repeated after the tenth day A signif icant reaction may not be obtained until convalescence has begun

A differential diagnosis between Rocky Mountain spotted fever and the other rick ettsial diseases should not be attempted by means of the Weil Felix reaction *

Symptoms —*Incubation* —The incuba tion period in the more severe infections is two to five days and in the milder ones from three to fourteen days

Prodromal Stage —Before the definite on set of the disease there may be a few days of malaise accompanied by chilly sensations and loss of appetite The prodromal stage is more common in Idaho where the disease is less severe than in Montana The *onset* is usually accompanied by a chill and there are severe general pains referred to the bones muscles back and joints, particularly in the calf muscles large joints and lumbar region of the back Headache is common and severe The face is flushed the conjunc tivae injected and the tongue white coated with moist edges and tip Constipation is usual There is usually photophobia and there may be epistaxis A short dry cough is common The patient is frequently ill enough to take to bed on the second day of symptoms

TEMPERATURE —Before the initial chill there may be slight evening elevation of temperature Following the chill the tem perature rises fairly rapidly and reaches 102° to 104° F (38 8°–40° C) by the sec ond day It continues to rise gradually to a maximum of 104° to 105° F (40°–40.5° C) during the second week In very severe cases in the Bitter Root Valley temperatures from 106° to 107° F have been recorded The maximum temperature persists during the second week of the disease, with slight morning drops With recovery the tempera ture begins to fall at about the end of the second week, continuing by lysis, so that normal temperature is reached at about the end of the third week After recovery the temperature may be slightly subnormal for a few days In fatal cases the tempera ture may drop to normal or subnormal and then rise eighteen to twenty four hours be fore death which in severe cases usually takes place between the sixth and twelfth days of the disease

The PULSE is at first full and strong but gradually loses volume and strength, and increases in rapidity out of proportion to the fever The pulse rate ranges from 110 to 140 and may reach 150 a few days before death A pulse rate of 120 with a tempera ture of 102° F is not uncommon

The RESPIRATIONS behave very much as does the pulse They are rapid and out of proportion to the apparent severity of the illness usually 30 to 40 a minute but in creasing occasionally to 60 before death

The RASH appears usually on the third fourth or fifth day of fever most often on the third, occasionally as early as the sec ond or as late as the seventh day It appears first on the wrists ankles and back then on the forehead, arms, legs chest, and abdomen The efflorescence requires twenty four to thirty six hours although the eruption may appear still later than this on the palms of the hands, soles of the feet, and scalp The mucosa of the cheeks palate fauces and pharynx may show the eruption The tem perature is not appreciably affected at the time of the eruption but the subjective symptoms ameliorate The rash at first is in the form of rose colored macules 1 to 4 or 5 mm in diameter not elevated not pal pable and disappearing upon pressure The skin may be tender at the site of the spots The macules soon become deep red or purplish in color and increase in size often becoming confluent After a few days the rash begins to persist upon pressure and then becomes generally petechial in char acter Cutaneous and subcutaneous hemor rhages of considerable size occur frequently in severe cases and the skin in the second week of the disease may assume a glazed appearance Where the skin is thin as over the thighs a peculiar dusky reddish or bluish mottling may often be seen which

* See Typhus Fever for further considerations of the Weil Felix reaction

ing may be employed to reduce temperature in the absence of hyperesthesia Antipyretic drugs should be avoided Hypnotics such as morphine codeine and hyoscine may be recommended when the hyperesthesia restlessness and insomnia become of importance in the production of exhaustion All efforts should be directed toward keeping up the strength of the patient and hence the diet should be nutritious liberal and easily digestible particularly during the first stages of the disease Liquids should be given in abundance and a daily movement of the bowels secured by enemata or aperients Digitalis may probably be used to advantage as in pneumonia a few doses should be given at the onset of the disease in order to digitalize the heart and should be followed by others when the pulse rate becomes unduly high On theoretical grounds the transfusion of blood from an immune donor should be tried when opportunity occurs in the early stages of the disease

TRENCH FEVER

(*Quintan Fever Shin Bone Fever Wolhynian Fever His Werner Disease etc*)

Definition—Trench fever is a specific exanthematic louse borne infection characterized usually by a sudden febrile onset with pain and soreness in muscles bones and joints and by a tendency to relapse weeks or months after the primary attack The disease is remarkably protean in its clinical manifestations but is never fatal

History—The disease was first recognized in 1915 when it appeared on the western and eastern fronts during the World War possibly imported from an endemic focus in Russia. Evidence of its occurrence in previous wars is difficult to evaluate It constituted one of the major medical problems of the war because of the tremendous amount of disability which it caused, and was investigated intensively by a British and by an American commission Following demobilization the disease practically disappeared but presumably retains the potentiality of again becoming epidemic if similar conditions of overcrowding and lousiness should ever be reproduced A recent report (1941) of a small outbreak of trench fever among laboratory workers on whom supposedly normal lice were being fed in the process of making typhus vaccine suggests that a reservoir of the disease may still exist in lice

Epidemiology and Etiology—The responsibility of the body louse in transmitting the disease to man was established by both British and American commissions as a result of well controlled louse feeding experiments upon human volunteers The virus is present in the excreta of lice where it may remain infective for several months In the human patient during the active stage of the disease it is constantly present in the blood often in the urine and occasionally in the saliva and sputum The disease is transferable from man to man by intravenous inoculation of blood but not by rubbing blood into the broken skin

Experimental transfer of the infection from louse to man was much more readily effected by rubbing louse feces into the scarified skin than by merely allowing lice to feed upon human subjects Practically all virus free control lice became infective about nine days after feeding on febrile patients and in some instances infectivity appeared in lice fed upon apparently recovered patients ten or twelve weeks after subsidence of signs and symptoms

Regarding the nature of the etiologic agent there is strong but perhaps not conclusive evidence incriminating an organism (*Rickettsia wolhynica R pediculi R quintana*) the presence of which in the intestines and feces of lice was definitely correlated with infectivity by Bacot Arkwright and Duncan The principal difficulty in accepting this organism was its occasional occurrence (on the continent but not in England)

In endemic typhus it appears first on the chest and upper abdomen and usually spares the palms and soles and rarely involves the face and neck wrists and ankles

Animal inoculations and cross immunity tests may be necessary to decide which disease is encountered Male guinea pigs and male white rats should be used If possible at least 4 cc of whole blood should be injected intraperitoneally into each of several rats and guinea pigs A heavy exudate with an abundance of rickettsiae in the scrotal sac of either animal is strong evidence of endemic typhus if in the rat the evidence is conclusive If the animals react mildly, a final opinion can be given only after cross immunity tests following their recovery Serum from a convalescent patient with doubtful diagnosis may be tested in guinea pigs for protective value against the viruses of typhus and Rocky Mountain spotted fever in laboratories where these strains are at hand

Recently a specific complement fixation test using suspensions of cultivated rickettsiae for antigen has been devised

Prognosis—The severity of the rash in Rocky Mountain spotted fever is without prognostic importance Patients with severe nervous symptoms are to be regarded as gravely affected The critical period in the disease is toward the end of the second week and the pulse and respiration rates furnish the best guide in regard to the severity of the case A sudden increase in the white count as indicative of a secondary infection, usually means a fatal termination The mortality rates in various regions have been given above In all regions the disease is much more fatal in adults than in children and is most fatal in the aged

Prophylaxis—The general measures to control the disease are directed toward the reduction of numbers and the limitation of distribution of ticks The two methods of greatest practicability and which have met with some success in the Bitter Root Valley are the destruction of the small mammals which act as hosts to the larvae and nymphs and the dipping of cattle infested with adult ticks Clearing and cultivation of the land have made regions safe that were formerly unsafe Lands unfit for agriculture promise to remain sources of infection unless the ticks can be controlled by new methods The introduction of a fly (*Ixodiphagus caucurtei*) parasitic upon *Ixodidae* into a restricted region in Massachusetts in 1926 was effective in reducing the number of ticks in the years following Larger scale experiments in the Bitter Root Mountain country have not been encouraging

In some eastern regions a reduction in number of ticks could be effected by reducing the number of several species of wild mice which are host to the immature stages of *Dermacentor variabilis* Poisoned baits as employed by orchardists would seem most practicable Personal prophylaxis means the avoidance of tick bites This is not difficult for the casual traveler but is very difficult for those who work in tick infested regions A protective one piece working costume may be improvised by sewing trousers and shirt together The trousers should be worn inside heavy woolen socks with high laced boots It is also advisable to interpose a strip of greased felt or other absorbent material in the neck band and wrists Stripping and inspecting the body for ticks would greatly diminish the chances of contracting the disease as the tick is slow to attach and ordinarily remains attached for a short period before beginning the act of feeding

Exposed children should be inspected at noon and night When camping the bedding should be carefully inspected morning and night Ticks attached to the body should be removed at once by gently pulling them off with the fingers crushing them should be avoided An effective cauterizing agent like crude phenol should be introduced by means of a sharp pointed bit of wood into the point of attachment after removal of the tick Silver nitrate though less effective is easier to carry

The vaccine of Spencer and Parker has proved to be of definite value and should be given each year to persons liable to be exposed to the disease The immunity it gives lasts only about a year but it is sufficient to prevent or markedly ameliorate the disease A vaccine prepared from the yolk sacs of developing chick embryos (method of Cox) is now under trial

Treatment—There is no specific treatment The measures to be used are those employed in other continued fevers Bath

Pain and soreness in the muscles usually recur with each febrile relapse Lumbar pain is most apt to persist in the chronic stage of the disease Abdominal pain and tenderness probably of muscular origin are usually bilateral and more pronounced on gentle than on firm pressure This fact together with the palpable spleen rash and generalized pain and tenderness usually serves to differentiate the condition from appendicitis

Prognosis —The disease has no mortality Its duration is extraordinarily variable but about 85 per cent of all patients are able to return to work within two months of the time of onset It is believed that in about 5 per cent of all cases the disease becomes chronic necessitating a much longer period of time for complete recovery Recovery is apt to be delayed in the aged and in the *debilitated*

Diagnosis —During epidemics typical cases are readily diagnosed on the basis of the symptomatology outlined above The atypical abortive cases may be confused with influenza in the absence of the characteristic rash The mild character of respiratory symptoms and the enlarged hard spleen of trench fever are valuable differential criteria in such cases The differential diagnosis from appendicitis has already been considered The typhoidal type is differentiated from true typhoid by the negative Widal reaction and by the almost constant presence of mild to moderate leukocytosis rather than leukopenia In typhoid typhus and dengue fever the onset is more gradual than in trench fever and the rash usually appears several days later Spirochetal relapsing fever and *malaria are ruled out best by examination* of the blood for their specific etiologic agents In cases of the chronic type with tachycardia fatigue loss of weight and symptoms of neurasthenia diagnosis may be most difficult It is theoretically possible to establish strong presumptive evidence of trench fever by feeding carefully controlled lice on such patients and finding that they acquire *Rickettsia wolhynica*

Treatment —No well-established or rational specific treatment is available Pain and discomfort should whenever possible be controlled by such drugs as aspirin and phenacetin rather than by opiates Codeine is useful in cases of severe pain Insomnia can usually be controlled by hypnotics The patient should remain in bed under the best available hygienic and dietary conditions for a week or more after complete cessation of subjective and objective evidence of infection He should be kept under observation for several months, and returned to bed at the first sign of relapse Eventually work may be gradually and cautiously resumed

Prophylaxis —Prevention of the disease is largely a question of efficient delousing Destruction of the virus on clothing contaminated by louse excreta is also of primary importance Since the virus has been found to withstand moist heat at 70° C autoclaving is probably the most satisfactory method Disinfection of urine and sputum may be carried out by chemical *methods or by heat* Louse *proof garments* and rubber gloves should be worn by those attending patients or handling clothing Trench fever patients are best treated in separate wards It must be borne in mind that lice may become infected from apparently recovered individuals many months after the disappearance of symptoms

TSUTSUGAMUSHI DISEASE

(Japanese Flood Fever Kedani Disease Rural Typhus Tropical Typhus—Type K)

Definition —Tsutsugamushi disease is a *specific* mite borne infection characterized by a febrile course of two or three weeks duration a generalized cutaneous eruption

in lice which were not infective This objection could readily be met by assuming that this organism may at times occur in a nonvirulent form

The organism occurs extracellularly in the gut of the louse, thus differing from other pathogenic rickettsiae Since intracellular multiplication is usually regarded as an outstanding characteristic of this rather arbitrary group it is possible that the names assigned to the trench fever organism may eventually be withdrawn For the present however, they have considerable pragmatic value and for this reason should be retained

Important confirmatory evidence of the etiologic role of *R wolhynica* was obtained incidentally through the illness of Mr Bacot while in Warsaw as a member of the Typhus Research Commission in 1919 A strain of lice absolutely free from organisms brought from England as a control for the typhus work was being fed on Mr Bacot at the time when he developed an illness considered typical of trench fever by well qualified clinicians This infection was presumably acquired from local Warsaw lice which were also being fed on Mr Bacot at the time Twenty days after the onset of his illness the rickettsia free control lice being fed on Mr Bacot developed large numbers of *R wolhynica* and he continued to infect this control strain of lice for a period of several months

It seems justifiable on the whole to regard *R wolhynica* as the presumptive cause of trench fever The lack of a susceptible experimental animal makes absolute proof impossible at present

Morbid Anatomy —Postmortem studies have not been made since the disease is never fatal Examinations of excised macules from the skin have apparently shown no important specific changes The spleen is usually enlarged and firm to palpation *Rickettsiae* have not been satisfactorily demonstrated in human tissues

Symptoms —INCUBATION PERIOD —Evidence obtained from the inoculation of volunteers indicates that the usual incubation period is from ten to twenty days with extreme limits of five to thirty eight days depending largely on the dosage employed Prodromal symptoms of headache and general malaise may occur at any time after *the first twenty four hours of the incubation* period

ONSET —The onset is usually acute with chills and a rise in temperature to 102° or 103° F Severe headache usually behind the eyeballs and complete anorexia are almost constant at this stage Nausea and vomiting sometimes occur Laryngitis and bronchitis may be present but are rarely severe Perhaps the most characteristic symptom is severe 'myalgic' pain in various parts of the body, but most prominent in the lumbar region and legs There is also muscular soreness pain in rotating the eyeballs, conjunctivitis and photophobia Occasionally the *onset is insidious and symptoms of* neurasthenia and tachycardia may first call attention to this more chronic form of the disease

Course of the Disease —The progress of the disease is remarkably vagarious The fever and symptoms may last only two or three days or may be typhoidal in character lasting two or three weeks A very common form is that in which there are two febrile periods of three to five days each with twelve to twenty four hours of remission between them Again there may be short febrile periods of only twenty four to thirty hours, recurring regularly every five days for a variable period of time Relapses are prone to occur several weeks or several months after apparent recovery In most cases immunity appears to develop eventually, although relapses have been noted after several years

The characteristic *rash* usually appears during the first twenty four hours and thereafter comes and goes with fever even in the cases of late relapse It is composed of red macules 2 to 10 mm in diameter appearing first on the chest and abdomen and usually confined to those regions although it may involve the entire trunk The extremities are occasionally involved but the face always escapes

The pulse rate during the initial acute attack is increased in proportion to the fever but may be relatively much higher in late relapses A sharp increase in the pulse rate often precedes and may be the only objective evidence of a relapse Tachycardia and dyspnea on exertion are common symptoms in the more chronic form of the disease

protective suits and chemical sprays are obvious methods of prophylaxis Preventive vaccination along the lines developed in typhus and spotted fever is theoretically possible but has not been attempted Immune serum therapy is in the experimental stages in all rickettsial diseases

In general treatment should be symptomatic and supportive the principles being identical with those employed in other rickettsial diseases (typhus and spotted fever) Cauterization of the site of attachment of the vector is probably useless unless done almost immediately after detachment

In experimental animals the sulfonamides cause lowered resistance to typhus and spotted fever and present evidence strongly suggests that these drugs are contraindicated in all rickettsial diseases

CARRION S DISEASE

(*Bartonellosis Oroya Fever Verruga Peruviana*)

Definition —Carrion s disease is a specific arthropod borne infection caused by a minute Rickettsiae like micro organism and characterized clinically by an acute febrile anemic stage (Oroya fever) followed, several weeks later by a nodular cutaneous eruption (verruga peruviana) Either of these stages may be inconspicuous or apparently absent and for this reason the two clinical pictures were originally regarded as separate diseases

Distribution and Epidemiology.—The disease has been found only in narrow valleys in the Andes Mountains at altitudes between 2000 and 9000 feet Until recently it has been largely confined to Peru with a few cases in Ecuador Chile and Bolivia, but in 1939 a serious outbreak was reported in Colombia, suggesting that the distribution may be more widespread than has been supposed The distribution of the disease corresponds in general to the habitat of its probable sandfly vectors *Phlebotomus noguchii* and *P verrucorum* but in Colombia lice and ticks have been suggested as vectors Many natives of the infected areas have asymptomatic infections revealed only by blood culture Severe epidemics in Peru have often been associated with the importation of railroad workers from noninfected regions A reservoir for the infection in lower animals has been suspected but not found

Etiology—The etiologic agent was first seen in the red blood cells in the anemic form of the disease by Barton in 1909 and was named *Bartonella bacilliformis* by Strong *et al* in 1915 It was cultivated in Noguchi s leptospira medium by Noguchi and Battistini in 1926 Noguchi s original evidence of the etiologic identity of Oroya fever and verruga peruviana was further confirmed by new methods of approach by the Harvard 1937 Expedition to Peru and the unity of the two conditions must be considered as established beyond a reasonable doubt

Rats dogs and a number of other mammals suffer from latent bartonella infections which after splenectomy evolve into a severe anemia comparable to Oroya fever Cutaneous lesions apparently do not occur in lower animals Except for the transmission of human bartonella infection to monkeys each species of bartonella appears to be completely specific for the species of animals from which it is recovered

and usually by an ulcerative and necrotic lesion at the site of attachment of the vector with swelling and tenderness of the regional lymph nodes

Distribution —*Originally described in the* flood basins of the large Japanese rivers, the disease is now known to occur also in Formosa, Sumatra the Malay Peninsula, the Bako Islands the East Indies and the Philippines Tropical typhus—type K (rural typhus) is apparently a strain variation of tsutsugamushi It should be borne in mind that statements regarding the distribution of rickettsial diseases have only temporary value During the past twenty years, diseases of this group believed to be sharply restricted to definite areas, have been found to occur often in a slightly modified form and with different insect vectors and intermediate mammalian hosts in regions widely separated from one another Whether this is the result of more careful world wide study of obscure febrile diseases or of migration of infected mammalian hosts has not been determined

Etiology and Epidemiology —Recent work by Japanese investigators has established the rickettsial nature of the disease rendering other theories of historical interest only The disease may be propagated serially in rabbits by the injection of the virus into the testicle where the minute bacterium like intracellular parasite inhabits the interstitial cells or into the anterior chamber of the eye where it develops within the corneal endothelial cells overlying *Descemet s* membrane The etiologic agent has been named *Rickettsia nipponica R orientalis* and *R tsutsugamushi* by different Japanese schools but its relationship to other rickettsiae has not been fully studied and its assignment to a permanent systematic status is perhaps premature

The disease outside of Japan proper occurs in regions which are being cleared for cultivation as well as in river basins The role of the larval form of the mite (*Trombicula akamushi*) in carrying the infection to man and the existence of a rodent (vole) reservoir are two generally accepted facts which make the epidemiologic problems similar to those involved in spotted fever and typhus

Morbid Anatomy —As in other rickettsial diseases there are no distinctive gross lesions in the viscera The local lesion is said to be a coagulation necrosis, probably resulting from endangitis The spleen is en*larged and* there is generalized visceral congestion

Symptoms —The local lesion is a sharply *defined round ulcer several millimeters in* diameter with a black necrotic center and surrounding red areola It usually develops two or three days after the infection by the mite and is *followed in a few days by marked* inflammation of the regional lymph nodes and generalized symptoms (The bite of *Trombicula akamushi* when noninfective produces local inflammation and pain *without* necrosis)

In the early stages of the disease, general malaise headache anorexia insomnia and photopsia are most constantly present Joint pains and epistaxis occur occasionally When the local lesion and lymphadenitis are ab*sent as is often the case in mild epidemics* occurring outside of Japan proper, the febrile reaction develops more rapidly but the course of the disease is shorter and the mortality lower than when these initial signs are present Leukopenia is an almost constant finding in severe cases The rash which is of the maculopapular type is distributed over the entire surface of the body and is not associated with itching or pain Symptoms vary greatly in severity in different local epidemics the mortality ranging from 3 to 60 per cent

Diagnosis —The characteristic local lesion and bubo and the Weil Felix reaction (ag*glutination in moderately high titer* with OX K and negative results with OX 2 and OX 19) are the important features in differentiating the disease from typhus and spotted fever Unfortunately in the mild epidemics occurring outside of Japan proper these criteria are less constant and consequently of less value Low mortality low agglutination titer absent or inconspicuous primary lesion and rash and absence of leukopenia are characteristic of these atypical forms of the disease Animal inoculation crossed immunity tests and other special laboratory studies may be necessary to establish a diagnosis in such cases

Prophylaxis and Treatment—Eradication of the mite and avoidance of its bite by

sionally they are seen in large numbers on the mucous membrane of the mouth and pharynx They are ovoid or spherical in shape and usually half buried in the subcutaneous tissue and covered with thin bluish epidermis which often breaks down leading to ulceration and secondary infection Healing occurs with little or no cicatrization after a period of several weeks The cutaneous stage has no mortality *per se* The possible complications are hemorrhage and local secondary infection neither of which is apt to be serious

Diagnosis —The diagnosis is made from a history of residence in an infected area and on the clinical pictures described above Finding bartonellae in the erythrocytes in blood films establishes the diagnosis in the anemic stage In the cutaneous stage a nodule may be excised and bartonellae may be demonstrated in the endothelial cells Blood cultures in Leptospira medium are positive in both stages Rarely the cutaneous nodules may appear a year or more after an uneventful visit to an infected area Yaws which may simulate verruga peruviana can be differentiated by the demonstration of the specific organism

The blood smear in addition to the infected red cells shows a leukocytosis with a normal differential count except for the presence of numerous myeloblasts The anemia is of the megaloblastic type with a high color index and many megaloblasts normablasts poikilocytes and polychromatophilic cells

Treatment —The treatment of the febrile anemic stage of the disease should be supportive and symptomatic as is any other acute infection Transfusions of whole blood are of undoubted value in severely anemic cases The transfusion of blood from recovered cases has not been demonstrated to be of definite value Arsphenamines which apparently exert a favorable effect on bartonella infection in rats have been disappointing in the human disease and are probably of doubtful value Sulfa drug therapy is not beneficial in rat bartonellosis Liver therapy would seem rational but in practice does not appear to be of value Iron should be given during convalescence The cutaneous stage rarely requires treatment except general cleanliness Excision of necrotic, secondarily infected nodules may occasionally be indicated

Prophylaxis —Since the sandfly does not emerge from the rocky caves in which it lives until after dark it is possible for visitors in the infected areas in Peru to avoid infection by descending below an altitude of 2000 feet or ascending above 9000 feet to spend the night If it is necessary to spend the night in the infected area reasonable security against infection can be obtained by screening The possibility of other insect vectors in Colombia has already been commented on The nature of the country in the Peruvian Andes would scarcely permit a successful attack on the sandfly vector

THE BACTERIAL DISEASES

PNEUMOCOCCAL INFECTIONS

INTRODUCTION

THE pneumococcus is one of the most prevalent of the pathogenic bacteria in the temperate zone It occurs in a comparatively harmless form in the buccal cavity of man and of many animals In such conditions its virulence may be almost nil On the other hand where it acts as the cause of disease it may become one of the most virulent of all the bacteria killing mice in doses as small as one ten millionth cubic centimeter of broth culture The importance of the pneumococcus as a cause of infection is due

Morbid Anatomy—Postmortem studies of fatal cases of the anemic form of the disease show pallor, enlargement of the spleen and lymph nodes and a megaloblastic hyperplasia of the bone marrow The endothelial cells lining small vessels in the lymph nodes, spleen, liver, bone marrow adrenals kidneys and many other organs are greatly swollen and with suitable fixation and staining are seen to be packed with small bacillary and coccoid organism (bartonellae) often occurring in clusters Organisms are also present in the erythrocytes Cutaneous nodules are rarely seen at autopsy, since they commonly do not appear until convalescence from the anemic phase is well established Microscopically the cutaneous nodules have the appearance of rapidly growing capillary hemangiomas Bartonellae may be demonstrated within the endothelial cells with suitable technic Clusters of degenerating bartonellae in the cytoplasm may stain uniformly and resemble inclusion bodies

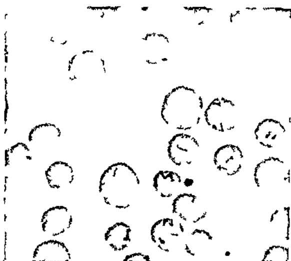

Fig 12—Carrion's disease Giemsa stained blood films showing *Bartonella bacilliformis* in red blood cells Both bacillary and coccoid forms are seen

Symptoms and Course of the Disease—*Anemic Form (Oroya Fever)*—The incubation period is believed to be fourteen to twenty one days In severe cases the onset is sudden, with intermittent fever ranging to 104° F progressive pallor emaciation prostration rapid pulse and dyspnea Muscle and joint pains headache and insomnia are also common symptoms and delirium and coma are apt to be terminal manifestations A petechial cutaneous eruption *occasionally* appears during the febrile period The erythrocyte count may fall from normal to less than 1 000 000 in four or five days, more rapidly than in any other condition exclusive of actual hemorrhage Examination of alcohol fixed Giemsa stained blood films shows bartonellae in the erythrocytes in large numbers, 90 per cent of the red cells frequently containing from one to fifty or more organisms Many reticulocytes and nucleated red cells are present in the blood In the severe form of the disease described above the mortality is 90 to 95 per cent Secondary infection, particularly with paratyphoid bacilli has been emphasized as an important factor in fatal cases, but this view was not substantiated by the author's personal observations The average duration of this anemic stage of the disease is from one to three weeks occasionally the condition of the patient remains critical for a period of eight to ten weeks Convalescence is accompanied by a disappearance of the organisms from the red cells and rapid blood regeneration, but blood cultures may be positive for many months after apparent recovery Reliable evidence indicates that *most if not all of the cases which recover* from this febrile anemic stage develop cutaneous nodules (verrugas) during or even after apparently complete convalescence

Cutaneous Form (Verruga Peruviana)—This form of the disease characterized by cherry red hemangioma like cutaneous nodules may follow the severe anemic form, or may occur in individuals who have had no previous symptoms Intermediate cases are also frequently seen in which there is moderate anemia with rare bartonellae in the red cells slight or no fever and only a few days of malaise *followed weeks or* months later by typical cutaneous eruption The appearance of the cutaneous nodules may be immediately preceded by a few days of moderate fever with joint pains

The cutaneous nodules (verrugas) are commonly 2 to 10 mm in greatest diameter but range up to 3 or 4 cm They may be single or extremely numerous These are most numerous on the head hands feet and lower arms and legs, and are rare on the thighs abdomen or lower chest Occa

growth Furthermore the body fluids and at least some of the tissues of patients with pneumococcal infection contain demonstrable quantities of SSS The amount of SSS appearing in the urine varies with the patient and has considerable prognostic importance

The *virulence* of the pneumococcus can be rapidly increased by repeated passage through animals When freshly isolated from serious infections it usually possesses high virulence but this is gradually lost by growth on culture media In human infections the pneumococcus is prone to be a secondary invader but it can act as a primary infectious agent under certain circumstances In ordinary times about 75 to 80 per cent of all pneumonias are caused by some type of pneumococcus The pneumococcus is therefore primarily the specific agent in the etiology of lobar and lobular pneumonia However the pneumococcus is responsible for a considerable amount of morbidity outside of the lungs The acute respiratory infections of children are often complicated by pneumococcal infections in the middle ear and mastoid Pneumococcus Type III infections in this locality are particularly serious especially when they are complicated by thrombosis of the lateral sinus or brain abscess Pneumococcal meningitis is seen most frequently as a complication of pneumonia but may follow middle ear or sinus infection When secondary to pneumonia pneumococcal bacteremia is responsible for the secondary invasion of the meninges Pneumococcus meningitis was formerly fatal in almost 100 per cent of cases but the introduction of sulfonamide therapy has changed the picture somewhat An increasing number of cases have been cured when treated early with sulfathiazole or sulfadiazine by the oral or intravenous route This is particularly true of those cases which are secondary to mastoiditis Acute pneumococcal infection of the accessory sinuses is a frequent complication of the common cold Pneumococcal bacteremia of cryptogenic origin is encountered usually in children It is conceivable that in these cases the pneumococcus enters the body through the lungs without inducing a local lesion It is much more probable however that some primary focus of infection has been overlooked (tonsils teeth middle ear gallbladder and so on) Pneumococcal peritonitis may be secondary to pneumococcal infection in the appendix or gallbladder, or the infection may gain entrance through the fallopian tubes Subcutaneous pneumococcal abscesses are occasionally seen in the course of a septic pneumonia at the site of hypodermic injections of camphor in oil or other oily medicaments

The role of pneumococcal infections as a cause of death has been amazingly diminished by the introduction of sulfonamide therapy This is conspicuously true in the field of pneumonia but the statement holds for other types of pneumococcal infection as well The details of sulfonamide therapy will be discussed under the treatment of pneumococcal pneumonia

PNEUMONIA

Definition —An infectious inflammatory condition of the lung caused by pathogenic bacteria and characterized by the formation of an exudate in the interstitial and cellular portions of the lung As a result of this exudate more or less consolidation of the lung tissue takes place The clinical symp

largely to its capacity to produce pneumonia in man as well as in many of the animals Under certain circumstances however it is capable of attacking not only the lungs but almost any organ in the body

History —The pneumococcus was first isolated in 1881 by Pasteur and almost simultaneously by Sternberg in this country It was not until 1884 however that Frankel demonstrated its importance as the cause of lobar pneumonia His observations were confirmed by Weichselbaum in 1886

Bacteriology —The pneumococcus is a minute lance shaped grampositive coccus, which usually grows in pairs but sometimes, especially when cultured on artificial media in the form of chains It possesses a capsule which can be demonstrated in both body fluids and cultures The pneumococcus grows best on media containing blood or serum On blood agar plates it produces a flat grayish colony surrounded by a light green zone In plain broth, or in blood broth it grows diffusely throughout the medium The pneumococcus is distinguished from *Streptococcus viridans* by its solubility in bile and its ability to coagulate inulin The pneumococcus is extremely virulent for mice rats rabbits and monkeys On the other hand chickens and pigeons have a very high immunity against the germ The pneumococcus does not produce a toxin in the ordinary sense of the word When it is grown in media containing hemoglobin, the latter is changed into methemoglobin

Neufeld and Handel were the first to show *serologic differences* between certain pneumococcal strains and to establish two distinct types of organisms In 1913 Dochez and Gillespie by means of protection and agglutination tests subdivided all the pneumococci into four groups A somewhat similar division of pneumococci was made about the same time by Lister in South Africa Dochez and Gillespie recognized that Types I II and III were specific biologically while Type IV was a sort of waste basket group into which the remaining pneumococci were thrown In 1927 however Cooper Edwards and Rosenstein undertook a classification of the so called Group IV pneumococci Cooper and her associates were finally able to identify thirty two specific biological types of pneumococci The most prevalent of these are Types I II and III though Types IV V, VI VII VIII and XIV are rather frequently encountered in disease processes especially pneumonia The classification of pneumococci into thirty two serologic types has not exhausted the possibility of still other types A type XXXIII has already been described and not infrequently pneumococci are isolated which cannot as yet be identified as members of any generally recognized type

A good deal has been written about the *convertibility* or "mutability of one type of pneumococcus into another type either in the body or under cultivation While mutations can undoubtedly be achieved by artificial laboratory conditions it is not clear that the pneumococcus can undergo this transition under natural conditions in the animal body It should be noted however that a virulent pneumococcus under certain conditions can be transformed into an avirulent form When such a conversion takes place it is accompanied by loss of type specificity This process of dissociation is accompanied by a number of changes in the growth characteristics of the organism The virulent form is usually referred to as a smooth or S form because its colony has a smooth glossy appearance The avirulent form is called the rough or R form as its colony has a rough and dull appearance

The *chemistry* of the pneumococcus has received a great deal of investigation during the last thirty years There are three important chemical constituents the *protein* and the carbohydrate of the cell body and the polysaccharide of the capsule The carbohydrate is usually referred to as the C substance the polysaccharide of the capsule as the *soluble specific substance* or SSS The protein is apparently the same in all pneumococci, regardless of type or virulence It is capable of stimulating antibody reactions in animals but these antibodies are *lacking in type specificity* The specific polysaccharides of the capsule have received special study Each carbohydrate is distinct and specific and apparently is responsible for the serologic differentiation of pneumococci into types It has also been shown that pneumococci owe their virulence in large measure to the specific capsular polysaccharide Only virulent pneumococci produce considerable quantities of capsular carbohydrate during

Anatomic Classification—The anatomic classification of pneumonia is based upon the type of inflammatory lesion produced in the lung by the infectious agent

(1) Lobar pneumonia is characterized by a massive consolidation which usually involves all or the greater part of the lobe Frequently several lobes are involved in the process Ninety five per cent of lobar pneumonias are caused by some type of pneumococcus

(2) Bronchopneumonia is an inflammation of the terminal bronchioles and terminal air vesicles Part or all of the lobule may be involved In the majority of instances both lungs are affected with maximum involvement usually occurring at the bases Sixty to 70 per cent of bronchopneumonias are caused by some type of pneumococcus Streptococcus and other pathogenic bacteria are responsible for the remainder Suppurative bronchiolitis is an important feature in some cases of bronchial pneumonia especially those caused by the *Streptococcus hemolyticus* or *Hemophilus influenzae*

(3) Lobular pneumonia is practically synonymous with bronchopneumonia as the infection involves small groups of lobules in various parts of the lung tissue When these lobules coalesce as they frequently do into larger patches we have a condition often referred to as *confluent lobular pneumonia* and when this is sufficiently extensive it may be almost indistinguishable from lobar pneumonia

(4) Central Pneumonia.—This is usually an atypical lobar pneumonia in which the area of consolidation is situated near the hilum Because of this location frank physical signs are usually not present

(5) Interstitial pneumonia is not characteristic of any particular type of bacterial infection The pneumococcus streptococcus *Hemophilus influenzae* or even a virus may produce an interstitial type of pneumonia In interstitial pneumonia the exudate is located as the name implies in the interstitial frame work of the lung and there is comparatively little exudate found in the alveoli

(6) Aspiration pneumonia is almost synonymous with postoperative pneumonia The aspiration of material from the mouth produces a peculiar type of bronchial pneumonia not associated with any particular species of bacterial infection Contributing factors to aspiration pneumonia are surgical operations and diseases in which eructations and vomiting occur, or in patients whose tracheobronchial reflexes are dull thus allowing aspiration of regurgitated stomach contents At autopsy the aspirated gastric contents can often be demonstrated in the bronchial tree

(7) Hypostatic pneumonia is frequently seen as a terminal event in patients with longstanding heart disease or other chronic ailments conducive to chronic passive congestion of the lungs At postmortem the posterior portions of the lungs are consolidated and on section ooze large quantities of dark red bloody material The infection is terminal and usually caused by some organism of low virulence such as a higher type of pneumococcus or the *Streptococcus viridans*

Etiologic Classification—The various forms of clinical pneumonia may be classified according to the etiological agent responsible for the infection Usually a single microorganism is responsible though not infrequently two or more species may be isolated from the infected tissue

(1) Pneumococcal Pneumonia.—This is by far the commonest type of pneumonia in ordinary times In certain years there may be an epidemic of streptococcus pneumonia influenzal pneumonia or so called virus pneumonia but generally speaking pneumococcal pneumonia comprises the great bulk of acute infections of the lungs

(2) Streptococcus haemolyticus pneumonia makes up 2 to 3 per cent of the entire group though in some winters the incidence may be higher

(3) Staphylococcus aureus pneumonia is rare not over 1 per cent of all cases and is usually though not always of the bronchial type

(4) Friedlander's bacillus pneumonia constitutes 1 to 3 per cent of all cases and is characterized by a lobar type of consolidation

(5) Hemophilus influenzae pneumonia produces a peculiar type of bronchopneumonia characterized by peribronchiolitis and hemorrhagic exudate

(6) Tuberculous pneumonia may be of either bronchial or lobar type It should always be thought of in any pneumonia which is limited to one or both upper lobes

toms vary to some extent with the type of infection Pneumonia may be either primary or secondary, and the character of the lesions produced either massive or patchy

Incidence and Distribution—Pneumonia is one of the most serious infectious diseases to which man is heir It is widely prevalent in the United States Great Britain, and other civilized countries It is very difficult to estimate the incidence of the disease, but the figures on its mortality rate can be looked upon as fairly reliable For many years pneumonia ranked third as the cause of death in the registration area of the United States but examination of the accompanying chart on pneumonia mortality for New York State will show that there has been a steady decrease in the pneumonia death rate since the influenza epidemic of 1918 and that this decrease has been considerably accelerated during the last five years a phenomenon which no doubt can be attributed in part to the introduction of sulfonamide therapy At present the death-rate of 40 per 100 000 is about one fifth of the figure reported for the year 1907 an amazing decrease in fatalities from one of man's most dangerous infections

Pneumonia is particularly prevalent in cities It is a disease of the temperate zone though it may occur in the tropics A cold damp, changeable climate predisposes to the disease When it occurs in a warm climate such as that of Panama, it is doubtless referable to sudden changes of temperature Pneumonia is a disease of the late winter and early spring In New York City January February and March are the months during which the disease occurs most frequently July August and September show the lowest incidence

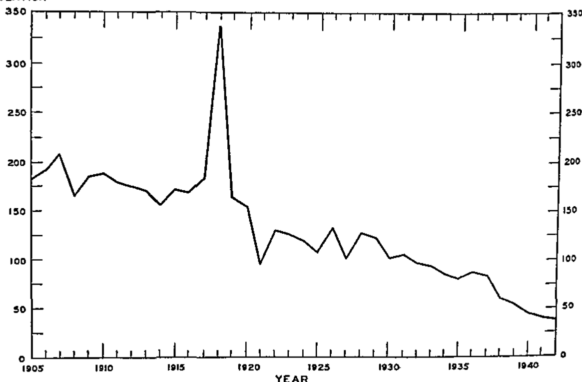

Fig 13—Trend in pneumonia mortality New York State 1905–1942

Classification of Pneumonia—The various forms of pneumonia may be subject to either an anatomical or an etiological classification Previous to the development of modern bacteriological methods physicians were dependent almost entirely on an anatomical classification In recent years however more accurate knowledge of the various bacterial agents concerned in pneumonia has led to a fairly accurate classification of pneumonia on an etiological basis

Personal Condition—Fatigue is one of the most important predisposing factors, especially when chilling of the body takes place after profuse perspiration Hunger is another important factor Debility and emaciation render individuals more susceptible to the pneumococcus In our large cities alcoholism is responsible for a great many cases

Weather—Sudden drops in temperature predispose to pneumonia—exposure to cold of any kind is undoubtedly an important factor The combination of cold and dampness such as occurs in the early spring affords conditions most favorable to contracting the disease

Previous Attacks—Pneumonia as a disease shows a definite tendency to recur but patients are usually immune to the type with which they have been infected

Acute Respiratory Infections—Pneumonia is rarely seen as a primary infection In nearly every case the patient gives a history of a preceding upper respiratory infection usually coryza or influenza sometimes tonsillitis or sore throat

Epidemiology —True epidemics of pneumonia are rare They do occur under certain unusual circumstances where large groups of susceptibles are thrown together in close personal contact particularly at the pneumonia season and directly following a widespread acute upper respiratory epidemic Examples are the epidemics among the diamond miners of South Africa and the outbreaks among recruits when a new cruiser is placed in commission

Characteristically the disease occurs sporadically one case of pneumonia here another there with no known source of infection and no known contact with another case Since a large proportion of persons harbor pneumococci it was formerly assumed that these sporadic infections must be autogenous We now know that in the great proportion of cases this does not occur It is true that in terminal pneumonia and in postoperative pneumonia the invading pneumococcus may be the same as the strain which the patient had harbored normally But in the large proportion (more than 40 per cent) of lobar pneumonia cases the invading organism is either Type I or Type II These strains are seldom found in the throat of the normal person (less than 1 in 200) The strains of pneumococci normally found in the throat are relatively avirulent types such as Types VI XI and XIX (Type III, a common inhabitant of the normal throat, is an exception to this rule)

The patient with pneumonia does not infect himself nor is he infected from contact with another case of pneumonia Where does he pick up the virulent strains? The probable source of the infection is a normal carrier We now have evidence that this indeed is the source of infection of most cases Studies of Rosenau and Felton of Stillman and of Smillie and his associates have shown that intimate family contacts of a case of pneumonia will frequently be found to harbor the homologous strain Smillie s family studies in New York in 1930 showed that from 25 to 30 per cent of family contacts of Type I or Type II pneumonia were carriers of Types I and II respectively He brings out the interesting fact that the patient does not infect the family—on the contrary the family infects the patient Often the virulent strain of pneumococcus is brought into the family by one of its working members It promptly invades the whole family One child may develop an otitis media another a sinusitis a third will develop pneumonia The sputum will be typed and this will first call the attention of the family physician to the fact that Type I pneumococcus has entered the family The patient with pneumonia usually loses his virulent strain in early convalescence but the carriers in the family may retain their virulent strains for weeks or sometimes months

The pneumonia patient in the hospital does not commonly transmit his specific strain to his nurses physician or fellow patients Simple hospital isolation procedures are quite sufficient to control the transmission of pneumococcus infection from the patient No method has yet been devised to *control transmission from the carriers* Quarantine of the family is not feasible the search for carriers by laboratory methods is not practicable Thus as Cruickshank has pointed out the epidemiology of pneumonia almost exactly parallels that of *Meningococcus intracellularis* infections and control measures also are almost identical

Morbid Anatomy —The face and lips are livid and bloody fluid may ooze from the

(7) MISCELLANEOUS INFECTIONS of the lung associated with various specific infections, e g influenza, tularemia, coccidioidomycosis, moniliasis, and others are rare forms of pneumonia usually of the bronchial type

(8) VIRUS PNEUMONIA (so called primary atypical pneumonia) is now a well recognized entity A number of different viruses have been isolated

PNEUMOCOCCAL PNEUMONIA

(Lobar Croupous or Fibrinous Pneumonia, Bronchial Pneumonia Lobular Pneumonia)

Definition —An acute infectious disease caused by the pneumococcus and characterized by massive inflammatory exudate in one or more of the lungs The dominant clinical symptoms are chill fever pain in the chest and cough with expectoration of rusty sputum

One of the most important contributions to our knowledge of pneumonia is that of Dochez and Gillespie, who found that pneumococci are made up of a number of biologically distinct strains Up to the present time thirty three biologic types have been isolated The most prevalent of these are Types I II and III though Types IV, V VI VII VIII and XIV are rather frequently encountered as the etiologic agent in pneumonia The remaining types only occasionally act as the cause of pneumonia though they are not infrequently found in the throats of healthy individuals Pneumococcus Types I to VIII cause almost 80 per cent of all lobar pneumonias as the following table will show These figures have been compiled from our own records at Bellevue Hospital

INCIDENCE OF TYPES IN 5779 CASES OF PNEUMOCOCCAL PNEUMONIA

Types	Cases	Per cent
I	1642	28 4
II	704	12 2
III	691	11.9
IV	275	4 8
V	409	7 1
VI	95	1 6
VII	358	6 2
VIII	397	6.9
IX-XXXII	1208	20 9

It is rather difficult to make a clinical distinction between the various types of pneumococcal pneumonia However, Types I II and III are prone to follow a typical course with classic lobar consolidation and a high fatality rate Pneumococcus Type I infections are commonly encountered in young people whereas Type III pneumonia is rare in the young but commonplace in middle aged or elderly people Pneumococcus Type XIV pneumonia is particularly prevalent in infants Pneumonia caused by the higher types often runs an atypical course with only partial consolidation of the lobes Many of these pneumonias caused by the higher types are true bronchial pneumonias

Factors Predisposing to Pneumonia —*Age* —The most marked susceptibility to pneumonia occurs at the beginning and toward the end of life Young children *are more susceptible than older ones* The susceptibility increases gradually during adult life, becoming greatest in old age The United States Census report shows however that 51 2 per cent of all deaths from pneumonia occur between the ages of twenty and sixty five indicating that pneumonia also takes a heavy toll of human life during the years of greatest activity

Sex —Men and women are probably equally susceptible to pneumonia when living under comparable conditions The greater incidence in the male is due to a difference in other predisposing factors such as occupation exposure, and mode of life

Race —Negroes are more susceptible to pneumonia than are the white races This was demonstrated during World War I when the Negro troops suffered much more than the white from pneumococcus infections

Occupation and Mode of Life —Pneumonia like tuberculosis is most common among the poor and undernourished Individuals who are exposed to hardships and inclement weather are particularly prone to contract the disease In the Bellevue Hospital series day laborers and sailors were the two largest groups of wage earners represented Pneumonia is more prevalent in cities than in rural districts This is probably due however not so much to living in the cities as to existence of slum conditions in the centers of densely populated areas

lung is ordinarily moist with fluid blood and dark red in color due to the general congestion The actual extent of the bronchopneumonia is indicated by the number and size of the projecting reddish gray areas which may be either isolated or in groups or may occur in confluent patches the whole producing a characteristic mottled appearance If the section has been cut in the axis of one of the lobules it may show a racemose or grapelike arrangement corresponding to small bronchi and their associated groups of air cells Between the solid areas of lung is found tissue more or less normal in color and air-containing There are also bluish depressed areas consisting of collapsed air cells whose bronchus has become plugged with exudate These collapsed areas may be large and involve a considerable portion of a lobe Occasionally the opposite result is observed and small areas of emphysema are to be seen due to inspiratory distention of the air vesicles In children there may be marked emphysema of the unconsolidated lung This helps to explain the x ray findings Commonly several solidified patches coalesce and form large masses of consolidation The process of coalescence may be so extensive as to affect whole lobes or even a considerable portion of one lung giving rise to the so-called confluent bronchopneumonia If the process is the end result of a general bronchitis the large tubes are involved in the inflammatory process and their mucous membranes are swollen and congested and the lumen contains more or less mucopurulent exudate Ordinarily the consolidated areas are polygonal in shape with a darker red center due to peribronchial congestion In the center of such a patch small grayish white points are apparent and indicate the position of the bronchioles Pressure on such solid patches causes the appearance of yellowish mucopurulent drops of exudate which can easily be squeezed from the partially plugged bronchi The walls of the small bronchioles are congested and the latter contain fluid material made up of serous exudate cells and occasionally hemorrhagic products

Microscopic examination of sections through the consolidated areas shows the bronchioles filled with mucopurulent secretion consisting of swollen desquamated epithelium leukocytes bacteria and granular material The bronchial walls are swollen and thickened and are infiltrated with polymorphonuclear and mononuclear leukocytes In certain types of bronchopneumonia such as that accompanying influenza or following measles the interstitial inflammation is marked and extends into the peribronchial and interlobular connective tissue There is always more or less denudation of the bronchial epithelium the blood vessels are engorged and here and there is to be seen an irregular dilatation of the bronchial walls

Experimental Pneumonia.—Various investigators have produced pneumonia experimentally in animals by injecting pneumococci directly into the trachea and bronchi In monkeys the disease can be perfectly reproduced by intratracheal injection of various types of pneumococci It is almost impo sible to produce pneumonia by merely introducing pneumococci into the nose or pharynx The larynx appears to form a barrier which prevents the passage of pneumococci into the trachea except under certain conditions

Pathogenesis—There are some who hold that pneumonia like certain other infections is hematogenous in origin The only evidence however in support of such a view, is afforded by the few cases in which pneumococci have been isolated from the blood before physical signs of pulmonary involvement were present In view of the difficulty often attending the detection of the earliest pulmonary lesions this evidence is not of great value Furthermore Blake and Cecil have shown that in the experimental pneumococcus pneumonia of monkeys the pneumococci may enter the blood stream following intratracheal injection in some instances before the symptoms or physical signs of pneumonia have developed Attempts to produce pneumonia in animals by intravenous or subcutaneous inoculations of pneumococci have consistently failed On the other hand the more commonly accepted view that the mode of infection is by way of the air passages has received considerable confirmation from the experimental production of pneumococcus pneumonia in animals by intratracheal inoculations Recent experimental studies by Robertson indicate that the spread of pneumonia from one lobe to

nose and mouth The striking pathologic feature of pneumonia is the consolidation of the pulmonary tissue This may be limited to *one lobe but usually in fatal* cases two or more lobes are affected According to most statistical studies the right side is more frequently involved than the left In single lobe infections the right lower and left lower are implicated with about equal frequency In two lobe infections the combination of right and left lower lobes is by far the commonest

Lobar Pneumonia—At postmortem examination the lobes involved in the pneumonic process are larger than the unaffected lobes and fill up the greater part of the *pleural space They are congested and covered* with a deposit of fibrin and on palpation are much firmer than normal lung tissue When consolidation is complete the lobe has a consistency very much like that of liver The trachea and bronchi contain blood stained viscid sputum

The process in the lung passes through a series of stages known as (1) engorgement (2) red hepatization, (3) gray hepatization and (4) *resolution Two or more of these* stages are usually demonstrable in the same case at autopsy—the reason for this being that infection starts in one lobe and as the disease progresses, spreads to other lobes In the parts first infected the process is naturally more advanced than in the parts last infected

Stage of Engorgement—This is the initial stage of the infection and is rarely *seen at postmortem The lung is still* crepitant but less so than in the healthy state There is intense congestion of the tissue which is heavier than normal On section the cut surface oozes a large quantity of bloody frothy fluid Microscopic sections show congestion of all the blood vessels and engorgement of the *capillaries in* the alveolar walls with exudation of plasma and red blood cells into the alveolar spaces *During this* stage there is only moderate infiltration of leukocytes and these are chiefly in the perivascular and peribronchial lymph spaces and in the alveolar walls

Stage of Red Hepatization—In this stage the lobe becomes completely solidified with exudate The surface is dark red and covered with *fibrin* and the lung has the consistency of liver On section the cut surface is also dark red and rather dry and granular Microscopic examination now shows the alveoli filled with fibrin, in the meshes of which there are many red blood cells and polymorphonuclear leukocytes *During this stage the cells show very little* tendency toward disintegration Many pneumococci are found in the alveoli but phagocytosis is not active

Stage of Gray Hepatization—In this stage the lobe takes on a grayish yellow color usually mottled with patches of red On section the cut surface is of the same shade and on scraping the surface with a knife a thick purulent exudate is removed *The bronchi contain purulent sputum The* grayish color is due largely to the leukocytes which in microscopic sections are found in great numbers in the alveolar spaces The red blood cells and many of the leukocytes are undergoing disintegration There are still many pneumococci in the alveoli but phagocytosis is active

Stage of Resolution—This stage like the stage of engorgement is not often seen at *autopsy When resolution is well advanced* the lobe on section has a translucent jelly like appearance and comparatively little exudate is demonstrable on the cut surface Microscopic examination shows the alveoli to be only partially filled with cells Most of the fibrin and red cells have disappeared and the leukocytes which survive are in various stages of disintegration The most characteristic feature in this stage is the *considerable number of desquamated* epithelial cells in the alveoli and the regeneration of the epithelial lining of the alveolar walls

Lesions in Other Organs—The heart is filled with fibrinous coagula The spleen usually shows moderate enlargement The liver and kidneys are the seat of cloudy swelling *In fatal cases complicating infections* of pneumococcal origin are frequently discovered in the various organs Suppurative pleuritis and pericarditis endocarditis meningitis and arthritis are among the commoner complications encountered

Bronchopneumonia—The affected portions of the *lung are somewhat fuller* and firmer than normal and in most instances firm consolidated areas can be felt throughout the lung tissue The cut surface of the

change for five to ten days In a majority of cases the disease then terminates rather abruptly by crisis or lysis in the remainder the patient dies from sepsis, toxemia or some complication

The *chill* is one of the most characteristic features of lobar pneumonia and is usually the first symptom to make its appearance A definite chill occurs in approximately two thirds of the patients while the others usually give a history of only chilly sensations The chill may be *mild or severe*, usually lasting from fifteen to thirty minutes

Pain in the chest is also a very common symptom usually appearing shortly after along on a high plateau without much variation In the less prevalent types it is often irregular in this respect resembling streptococcus pneumonia In elderly persons the temperature is lower and may run an almost normal course The degree of fever is not a reliable measure of the seriousness of the infection indeed there is some evidence that a high fever is a distinct advantage to the patient in his struggle with the disease

The *cough* at the time of onset is of a dry, hacking character unless the condition has been preceded by bronchitis when it is productive of a purulent sputum The cough is apt to come in paroxysms and cause the

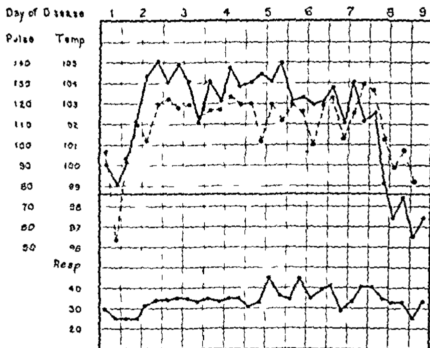

Fig 14.—Pneumococcus pneumonia Type II Crisis on eighth day Pulse curve indicated by dashes

the chill In some cases it precedes the chill and in still others the chill is absent and the disease is ushered in by the pain in the side This is usually located in the region of the nipple or at the base of the affected lung but in some cases it is referred to the abdomen and is accompanied by tenderness suggestive of appendicitis cholecystitis or peritonitis In upper lobe infections pain may be absent or referred to the shoulder

The *temperature rises rapidly* during the chill and usually *remains high ranging* between 103° and 105°F In the dominant types of pneumonia the temperature is apt to run patient much pain as the disease progresses it becomes less painful and more productive

The *sputum* in pneumonia is one of its most striking characteristics—the tenacious rust-colored sputum is pathognomonic and the diagnosis of lobar pneumonia can safely be based on its presence The character of the sputum changes as the diseases progresses From being pinkish or blood streaked at the beginning it becomes rusty and viscid on the third or fourth day Sometimes at this stage the sputum contains considerable bile which gives it a lemon or orange tinge As the disease passes into the

another is probably due to the passage of the infected exudate of the primary lesion from one main bronchus into another

Chemical Changes in the Blood—Inasmuch as the lungs are constituted to absorb oxygen and eliminate carbon dioxide, it is evident that a disease with widespread pulmonary involvement is apt to result in disturbance of these functions As far as carbon dioxide is concerned, the evidence bearing on failure of elimination is far from definite Lowering of the alkaline reserve has been frequently reported but only occasionally of more than moderate severity, whereas an actual shift of the hydrogen ion concentration of the blood to the acid side is a rare occurrence

It has been shown however that there may occur a deficiency of oxygen of such severity as to result fatally before the struggle between the forces of immunity has been decided Cyanosis has long been *prima facie* evidence of the existence of oxygen deficiency but it has been only the recognition of arterial anoxemia in quantitative terms that has led to an understanding of its importance With the introduction of arterial puncture the discovery of severe oxygen deficiency in the arterial blood of patients with pneumonia made possible the application of the physiology of 'oxygen want' previously worked out by Haldane Barcroft Schneider, and others

The arterial blood is normally 95 per cent saturated with oxygen In severe cases of pneumonia saturation of 75 per cent is not uncommon When the blood of a normal individual is lowered to this extent by breathing an atmosphere low in oxygen, a train of harmful symptoms becomes manifest The pulse rises approximately from seventy two to one hundred and twenty the patient breathes with increased rapidity *shallowness* and difficulty becomes irrational, suffers from nausea and vomiting at times becomes dizzy and feels weak and faint More severe anoxemia brings about coma, heart failure and death Mountain sickness and carbon monoxide poisoning are clinical conditions due *purely* to oxygen want In the latter the anoxemia frequently proves fatal In pneumonia symptoms of anoxemia are added to the symptoms of infection It is thus evident that arterial anoxemia may occur in pneumonia to such a degree as to have decidedly injurious effects

Other Chemical Changes in the Blood—There is considerable retention of chlorides during the active stage of pneumonia but it is not accompanied by an increase of chlorides in the blood There is also a definite increase in the amount of circulating fibrinogen

Symptoms—The symptoms of typical pneumonia vary somewhat with the age of the patient and the type of micro organism concerned in the infection There is no single symptom present in every case In the great majority of instances however the clinical picture is quite typical

The *period of incubation* is usually short probably not more than twenty four or forty eight hours In experiments on monkeys symptoms of infection appear in the animals eight to twelve hours after intratracheal injection

The *onset* is usually sudden, although occasionally it is gradual Prodromal symptoms of malaise sometimes occur but most patients are free from them and seem to be comparatively well up to the moment that acute symptoms appear For example an individual may go to bed feeling quite normal to be awakened in the night by a hard shaking chill or a sudden attack of sharp pain in the side The great majority of pneumonia patients give a history of having had an upper respiratory infection previous to the onset of pneumonic symptoms This however, may have subsided when the signs of pneumonia appeared

The *cardinal symptoms* of pneumonia are chill fever, pain in the side, cough, and the expectoration of rusty sputum Dyspnea is also a frequent symptom in the early stage The patient when seen twelve to eighteen hours after the chill is acutely ill The cheeks are flushed and the temperature is 103° to 104° F The respiration is rapid often painful on account of the pleuritic irritation The patient coughs frequently and may bring up a small amount of pinkish or rusty sputum Even when actual pain is absent the breathing is embarrassed Herpes is often present on the lip and the tongue is heavily coated If the temperature reaches 104° or 105° F the patient may become delirious These symptoms continue without much

piration decrease the cyanosis becomes less marked the cough is less distressing and is productive of considerable thick yellow sputum

Chest Signs at Onset —Inspection reveals limitation of movement of the affected side At this stage palpation and percussion are usually normal although there may be slight dulness over the involved area Pain frequently directs attention to the lobe affected and auscultation over this region reveals a characteristic feature of the early stage namely *quiet* or *suppressed breath sounds* Over the same area another early sign is the shower of fine crepitant rales heard at the end of inspiration or after coughing Bronchial voice and breath sounds are rarely heard during the first few hours of the disease

Chest Signs in a Well-developed Case —By the second or third day the typical signs of lobar pneumonia are usually present over one or more lobes Inspection of the chest reveals much less movement on the affected side The respiratory rate is rapid and accompanied by auxiliary action of the accessory muscles On *palpation* a pleural friction rub may sometimes be felt but the most important sign obtained in this way is the increased tactile fremitus on the affected side Sometimes this important sign cannot be elicited because of the accumulation of sputum in the main bronchus but this can be overcome by having the patient cough

Percussion —In the well-developed case percussion reveals dulness over the affected area In some instances the note may become almost flat differing very little from that obtained over a pleural effusion Over the uninvolved tissue just above a consolidated area percussion may elicit a note of tympanitic quality often referred to as Skoda s resonance

Auscultation —As frank consolidation develops the fine crepitant rales become less numerous and the normal vesicular breathing is replaced by bronchial breath sounds This type of breathing is very characteristic—high pitched rather harsh and with expiration of equal length with inspiration As in the case of vocal fremitus bronchial breathing may be absent or faint when the larger bronchi are completely plugged with exudate The voice sounds as well as the breath sounds usually have a frankly bronchial quality spoken of as *bronchophony* In certain cases, the voice sounds have a nasal quality—a condition termed *egophony* The whispered voice is also much intensified over the consolidated area

Chest Signs During Resolution —The respiratory rate approaches normal The dulness becomes less marked Vocal fremitus is usually slightly diminished Auscultation over the involved lung reveals many moist rales of the subcrepitant type commonly referred to as rales of resolution or consonating rales The voice and breath sounds gradually lose their bronchial quality and usually become diminished before finally returning to normal

Heart and Circulation —At the height of the disease the heart usually shows some enlargement particularly on the right side by reason of the extra burden placed upon it in forcing the blood through the congested lungs The rate is nearly always rapid and the rhythm regular Extrasystoles quite commonly occur and auricular fibrillation much less frequently The second sound over the pulmonic area is accentuated and sometimes a soft systolic murmur is heard at the apex In severe cases as the myocardium becomes exhausted by the toxemia and additional strain the heart sounds become less distinct and may take on a fetal character (embryocardia)

The blood pressure usually maintains a normal level but is apt to fall if the patient begins to lose ground A systolic pressure below 100 is a serious sign

In bronchopneumonia physical examination of the chest reveals small areas of dulness scattered throughout one or both lungs When fusion of these areas takes place the signs may assume all the characteristics of lobar pneumonia As a rule however, examination of the chest in bronchopneumonia reveals very few striking signs Over the small areas of dulness one may hear moist rales with occasional changes in the quality of the breath and voice sounds but, oftener than not dulness and rales constitute the only positive physical findings

Laboratory Findings —During recent years laboratory procedures have assumed increasing importance in the diagnosis and treatment of lobar pneumonia An early etiologic diagnosis is determined most readily

stages of gray hepatization and resolution, it becomes yellow and mucopurulent Microscopically the sputum contains mucus, red blood cells, pus cells, epithelium, and usually a considerable number of pneumococci

In bronchopneumonia the sputum is rarely rusty but in severe cases may have a frankly bloody appearance In the majority of cases the sputum in bronchopneumonia is mucopurulent In a certain number of cases of either lobar or bronchopneumonia the patient may go through the whole infection without having any sputum whatever

Dyspnea is one of the important symptoms of pneumonia The respirations are usually rapid shallow and labored and greatly aggravate the pleuritic pain The rate is almost always increased out of proportion to the amount of fever present Indeed, this type of breathing is a significant point in distinguishing pneumonia from other febrile conditions The respiratory rate usually varies from twenty five to forty per minute but may be even more when there is pain in the side or a marked grade of anoxemia A characteristic feature of the respiration is the peculiar expiratory grunt Inspiration is usually accompanied by dilatation of the alae nasi The respirations are rapid in proportion to the amount of lung involvement, they decrease in rate at the time of crisis although signs of consolidation may still be present

Herpes is observed in more than half the cases of pneumonia It appears most frequently on the lips, but may be seen about the nose on the cheeks or on the ears This symptom is often a significant one because of its early appearance and its value in differentiating between acute and chronic pulmonary disease

Nervous Symptoms —Delirium occurs in approximately 25 per cent of cases It is particularly common in alcoholic patients who in many instances must be forcibly restrained from getting out of bed Heavy drinkers often develop delirium tremens during the course of pneumonia a complication which renders the prognosis very grave It is not uncommon however particularly in mild forms of the disease for the mind of the patient to remain clear during the entire course In children the disease may be initiated by a convulsion and other cerebral symptoms strongly suggestive of meningitis Occasionally patients develop a postpneumonic psychosis in the form of a confusional insanity which, however usually terminates favorably in a short time

Gastro intestinal Symptoms —Nausea and vomiting are fairly frequent symptoms of pneumonia In some cases the illness is ushered in by an attack of vomiting Diarrhea is an unusual symptom Jaundice occurs in 5 to 10 per cent of cases The lighter form which is observed most frequently seems to have no significance—the deep jaundice which appears rarely is associated with a toxic hepatitis and makes the prognosis grave Tympanites is a frequent and troublesome symptom and is most marked in the severe cases It may be merely an expression of gastro intestinal disturbance but is more often the result of general toxemia When marked, it may add considerably to the respiratory embarrassment

In bronchopneumonia the symptoms do not differ essentially from those of lobar pneumonia The onset may be more gradual and the temperature more irregular Bronchopneumonia rarely terminates by crisis

Physical Findings —The physical signs in a typical and fully developed case of lobar pneumonia are quite characteristic but during the first twenty four or forty eight hours of the disease they may be almost if not entirely lacking With the development of specific treatment the early diagnosis of lobar pneumonia becomes more and more important and a careful search for the earliest physical signs is imperative

General Appearance —At onset the face is flushed the lips are cyanotic the skin is hot and moist herpes is frequently present on the lips or face Breathing is usually labored because of the pain in the side There is a dry hacking cough and the nostrils dilate with inspiration Frequently the patient gives a little grunt with each expiration The pulse is nearly always rapid and bounding and the rate proportionate to the degree of fever Sometimes the pulse is dicrotic but not so frequently as in typhoid fever Extrasystoles are quite common and complete irregularity is sometimes observed especially in elderly patients Toward the end of the disease in patients who are recovering the temperature pulse and res

may be occasionally permissible but should not be looked upon as a feasible routine

Other Bacteriologic Procedures —In some cases of pneumonia in which ordinary bacteriologic methods of obtaining the etio logic agent have failed the micro-organism may be recovered by cultures from some metastatic focus such as an empyema fluid or a secondary otitis or possibly an arthritis In still other cases of doubtful etiology the type can be determined by precipitin re actions with the soluble substance in the patient s serum or urine Finally there will remain a group of cases in which no pneu mococci can be isolated by any method

Blood —During the first two or three days of lobar pneumonia the total leukocyte count is usually elevated with a relative increase of the polymorphonuclear cells However it has been shown that this is not so accurate an index of the grade of infection or the amount of bone marrow response as is the increase in immature polymorphonu clear cells (shift to the left) The leukocyte count in pneumonia varies from 15 000 to 25 000 with the polynuclear cells ranging from 80 to 90 per cent Counts above 30 000 with the percentage of polynuclear cells in the nineties suggest some suppurative com plication such as empyema In severe over whelming infections some patients show a leukopenia from the first day of the disease In other instances patients who have been running a leukocytosis develop a terminal leukopenia during the last few hours of life In either case leukopenia is of grave import and indicates marked toxic depression of the bone marrow function

Dochez found that during the acute stage of pneumonia the coagulation time of the blood is usually prolonged There is also an increase in the quantity of circulating fibrin ogen and a sharp elevation of the sedimen tation rate of the red blood corpuscles

Palmer has shown that in lobar pneu monia there is an increase of excretion of total acids in the urine—not sufficient in amount however to indicate any marked degree of acidosis

Blood Culture —Pneumococci can be dem onstrated in the blood in approximately one third of all cases of lobar pneumonia The percentage of positive blood cultures in bronchopneumonia is considerably lower The prognosis in pneumonia is closely re-lated to the degree of bacteremia present Also its significance becomes greater when the bacteremia occurs late in the disease For example the presence of a few organ-isms in the blood early in the infection does not give as serious an outlook as does a late blood stream infection particularly when it is severe Under any conditions bacteremia indicates a grave situation and it is usually observed in connection with extensive lung involvement

Urine —In pneumonia the urine is scanty highly colored and of high specific gravity It usually contains a trace of albumin and in many cases a few casts These findings however as in many other febrile conditions simply indicate a toxic irritation of the kid neys In addition the urine shows a marked decrease in the content of chlorides—as much as 10 Gm of sodium chloride may be retained in the body during the course of the disease During convalescence there is usu ally an increased excretion of chlorides

X-ray Findings.—Usually by the time the patient has been admitted to the hospital and x ray examination has been made a dense homogeneous shadow is seen over the lobe or lobes involved This picture is fre-quently seen before physical signs of con solidation have appeared Where it has been possible to obtain repeated x ray plates early in the disease the shadow appears to extend from the hilum and spread out until it in volves the entire lobe Chest x rays show that frequently the diaphragm is elevated on the affected side and also indicate some en largement of the cardiac shadow Fluoro scopic examination shows limitation of the movement of the diaphragm on the side of the disease As the infection clears up the shadow slowly becomes less dense and less uniform Mottling of the affected lobe usu ally remains for some time after the toxemia and the signs of consolidation have entirely disappeared

Course and Termination —The fever persists for from five to ten days sometimes even longer During this time the tempera ture is often remarkably constant varying between 104° and 105° F day after day In old people the temperature is frequently lower and more irregular than in children and young adults

by bacteriologic study of the sputum Blood cultures are also considered a valuable aid both in diagnosis and prognosis The leukocyte count has acquired greater significance since the introduction of the Schilling index X ray examination is frequently employed and with the improvement in portable apparatus is found to be of great value in following the course of the pulmonary lesion

Sputum—The first step in the examination of the sputum should be a careful study of its gross characteristics It has been noted that in lobar pneumonia the expectoration usually has a typical rusty tenacious appearance Sputum from a case of bronchopneumonia is frankly purulent or it may be salivary in character A microscopic examination of direct films of the sputum should be made in order to rule out an acid fast infection and to note the predominance of a particular organism The sputum in pneumonia usually contains large numbers of pneumococci and because of this fact it is by studying the sputum that the bacteriologist determines the type of pneumonia with which the patient is infected The various laboratory procedures for typing pneumococci need not be described in detail The method now in common use is known as the Neufeld method it was first described in 1902 but did not come into general use until recently The reliability of the Neufeld method of typing has now been established by a number of observers

Neufeld Method—In carrying out the test a small loopful of sputum is smeared on a glass slide Quickly add to this two loopfuls of undiluted type specific rabbit serum and two loopfuls of Loeffler s alkaline methylene blue A thorough mixing is essential In many laboratories the sputum is tested for only the commoner types (I to VIII inclusive) If the specimen is to be tested against the entire thirty two types several combinations of monovalent antisera are first mixed and then added to the sputum Examination is made under the oil immersion lens with a strong light partially dimmed When pneumococci are mixed with a homologous antiserum the swollen sharply outlined capsules present an unstained greenish gray ground glass appearance In negative smears the pneumococci show no capsule or only a faint halo of light It is well to reserve final reading of the reaction for half an hour after the preparation has been made Typing by the Neufeld method should if possible be done on fresh sputum though reactions can still be obtained in sputums twenty four or even forty eight hours old If delay is inevitable the specimen should be stored in a refrigerator to prevent overgrowth by other bacteria

Other Methods of Typing—The Mouse Method—In some cases because of the scarcity of pneumococci in the sputum it may be impossible to determine the type of infection without first increasing the number of organisms In such cases it is well to inoculate a white mouse About 0.5 cc of sputum previously washed with sterile salt solution is injected into the peritoneal cavity of the mouse Three to four hours later the Neufeld technic is applied to small drops of the peritoneal exudate withdrawn by means of a sterile capillary tube or hypodermic syringe If pneumococci are still not present in sufficient numbers the procedure is repeated every hour until diagnosis can be made If only a small amount of peritoneal exudate is available preliminary tests should be restricted to those types for which therapeutic serum is available

Cultural Method—If a mouse is not available a tube of Avery's glucose blood broth is inoculated with some of the washed sputum After incubation for four to six hours it may be possible to determine the type of pneumococci in the culture by the Neufeld method

Throat Swab Method—When no sputum is available the type of pneumococcus may be determined by examination of material obtained on a throat swab By making the patient gag a small amount of mucus can often be caught on the end of a swab and smears made directly from this Some prefer to drop the swab at once into a test tube containing 2 to 3 cc of glucose blood broth and send the culture to the laboratory where after four to six hours of incubation the pneumococci present in the culture may be typed by the Neufeld method

Lung Puncture—Some writers recommend lung puncture when other methods of determining the type fail Such a procedure

cases x ray and fluoroscopic examination are of the greatest aid In all cases of empyema the diagnosis is finally determined by exploratory aspiration

Empyema should be regarded as a complication (1) occurring coincidentally with lobar pneumonia (2) occurring as one of a chain of complications including septicemia meningitis endocarditis pericarditis etc or (3) following pneumonia as a sole complication The seriousness of the condition *depends largely upon which one of these* situations is present When it appears early in the course of pneumonia the outlook is much more grave than when it occurs late or follows the disease When it is one of a chain of complications the prognosis is usually hopeless

SURGICAL TREATMENT is usually indicated in empyema A procedure which is now commonly used is the so called closed tube drainage in which a tube is inserted into the seventh or eighth intercostal space in the posterior axillary line The pus is allowed to drain slowly and when the cavity has been emptied it is irrigated every four hours with normal saline solution In cases in which the pus is too thick for satisfactory drainage irrigation with Dakin s solution is started at the time of the operation Encapsulated empyema may be treated in the same way However many surgeons feel that thoracotomy and open drainage is the procedure of choice in these cases Empyema when it occurs early and the exudate is thin as in hemolytic streptococcus infections may be treated by repeated aspirations followed by closed tube drainage when the pus becomes thick

Pericarditis is a serious complication of pneumonia occurring in 1 to 2 per cent of the cases It almost invariably terminates fatally The diagnosis is difficult to make for the symptoms and signs of pneumonia overshadow those of pericardial involvement. A friction rub synchronized with the heart beat and associated with pericardial pain is highly suggestive particularly if the rub persists when the patient is holding his breath In some cases a pericardial effusion may be detected but this will rarely be recognized without x ray photographs of the chest The treatment consists in removing the fluid by tapping and by surgical measures as indicated Pericarditis is one of the more serious complications of pneumonia The diagnosis is seldom made except at postmortem examination In a series of 131 fatal cases of Type I and Type II pneumonia, suppurative pericarditis was found four times Fibrinous pericarditis is a rather common incident in the course of pneumonia, but is of comparatively little clinical significance This is recognized by the presence of a transient pericardial friction rub

Endocarditis is also a comparatively rare complication and probably always fatal This condition may develop during the course of the pneumonia or it may come on gradually several days after the temperature has become normal It is more likely to occur in patients with chronic valvular heart disease Like other types of malignant endocarditis it runs a swift septic course with spiked temperature rapid pulse and often with chills and sweats The lesions are usually on the mitral valve although other valves may be involved Physical examination reveals a loud systolic murmur which increases in intensity as the disease progresses Signs of embolism appear in the different organs from time to time

Meningitis like pericarditis and endocarditis is rare and usually fatal It is often associated with the chain of severe pneumococcal complications which follow septicemia The prognosis in pneumococcus meningitis when treated with serum or sulfapyridine or both is not quite so hopeless as it previously was Indeed pneumococcus meningitis occurring as it frequently does in children in the absence of pneumonia is often curable by modern methods of treatment As a complication of pneumonia, meningitis is still of very serious import, though a few cases have been saved by sulfonamide therapy

Pneumococcus arthritis is a rare complication It develops only in cases with pneumococcus septicemia The condition is usually monarticular and generally takes on the character of a surgical joint In some cases however the joint does not suppurate and the condition clears up spontaneously

Thrombosis and embolism are both rare complications and usually occur in the femoral vessels Pulmonary infarcts occasionally are the cause of sudden death The

Pneumonia may terminate by crisis or lysis The typical crisis of pneumonia is one of the most striking features of the disease The patient struggling against a virulent infection, often appears on the verge of col lapse The whole organism seems to be af fected by the toxemia Suddenly the patient begins to perspire freely, there is a rapid drop in temperature to normal or subnormal, accompanied by a corresponding fall in the respiratory and pulse rate In a few hours the entire clinical picture is changed The patient looks and feels much better and drops off into a quiet sleep In some cases the true crisis is preceded by the so called pseudocrisis The temperature drops to normal or almost normal then rises again to 102° or 103° F for twenty four hours when the true crisis occurs

In many cases there is no definite crisis but the patient's temperature comes down gradually by lysis Both crisis and lysis ap pear to be an expression of acquired im munity on the part of the patient This opinion is corroborated by the fact that the various immune bodies make their appear ance in the blood of the patient at the time of crisis or just after it

In cases that terminate fatally the tem perature remains high the pulse becomes rapid and weak and the respiratory rate is accelerated These phenomena are referable usually to spread of the pneumonic process from one lobe to another until 3 4 or even all 5 lobes are involved in the infection The cyanosis becomes more marked the blood pressure falls and the patient shows every evidence of an extreme toxemia Blood cul tures taken at this time are usually positive and in most instances there is a drop in the total leukocyte count The immediate cause of death in pneumonia is usually circulatory failure which is presumably the result of vasomotor paralysis In some instances death appears to be referable to respiratory failure Various complications traceable to pneumococcal origin such as endocarditis pericarditis and meningitis are the immedi ate cause of death in not a few cases

Complications in pneumonia are numer ous and may be divided into two groups—those directly referable to the pneumococcus and those of toxic or other origin

Acute fibrinous pleurisy occurs so frequently in pneumonia that it can hardly be called a complication The characteristic friction rub of dry pleurisy is noted early in the disease in a good many cases and often causes the patient great discomfort Later on the fibrin may form a thick tena cious layer over the entire surface of the affected area

Pleurisy with Effusion —Acute serofibrin ous pleurisy is also a common complication of pneumonia It may develop early in the disease but is more apt to make its appear ance late in the course sometimes even after the crisis The presence of a pleural effusion is usually, but not necessarily indicated by some rise in temperature The physical signs are those of fluid in the chest If any con siderable amount of fluid collects, it should be aspirated

Empyema is the most frequent severe complication of pneumonia In the Bellevue Hospital series 5 1 per cent of the pneumo coccal pneumonias developed empyema The incidence of empyema was highest in Type I pneumonia, as the following figures show

	Cases	Percentage with empyema
Pneumococcus Type I	644	6 8
Type II	368	3.5
Type III	268	3 7
Misc types	633	5 0

Occasionally empyema of *Streptococcus haemolyticus* origin complicates a pneumo coccus pneumonia but this is rather rare

Pneumococcus empyema differs from that caused by the *Streptococcus haemolyticus* in that it usually develops after the more acute symptoms of pneumonia have subsided Empyema should be suspected in any case when after a day or two of normal or nearly normal temperature a fever of several de grees again makes its appearance accom panied by increase in pulse and respiratory rate and by a polymorphonuclear leukocy tosis Physical examination reveals the signs of fluid—absence of vocal fremitus flatness on percussion and diminished or absent voice and breath sounds Sometimes a pocket of pus develops between two lobes or in a small sacculated area This condition is known as *encapsulated empyema* The diagnosis is difficult particularly when the amount of pus present is very small In such

predisposes to another There are reports in the literature of patients who have had 20 or 30 attacks of the disease In our experience recurrences have usually been due to different types of pneumococcus Individuals have been followed who have had repeated attacks of pneumococcus Type III pneumonia In such cases a chronic focus of infection possibly in one of the sinuses should be looked for In a recent study by Strauss and Finland there seemed to be a greater tendency to recurrences at shorter intervals and from the same type of pneumococcus in patients who had been treated with sulfonamides than in patients not so treated

Special Clinical Varieties of Pneumonia —*Abortive Pneumonia*—Pneumonia occasionally runs a very short course—sometimes only twenty four to forty eight hours The early administration of serum or sulfonamides often produces this clinical picture

Pneumonia in the Aged—The onset is often insidious and the temperature may be normal or only slightly elevated The physical signs may be frank or very indefinite These patients often die suddenly of heart failure either during the infection or sometimes several days or even weeks after all signs of pneumonia have disappeared

Pneumonia Secondary to Other Diseases —A terminal pneumonia is seen very frequently in the course of chronic cardiac and renal disease diabetes pernicious anemia and other diseases In the Bellevue Hospital series 32 6 per cent of the cases occurred in patients with some chronic systemic disease The death rate in these cases was 46 4 per cent

Pneumonia is frequently seen as a complication of other infectious diseases particularly influenza and measles The lobar type of secondary pneumonia is nearly always of pneumococcal origin Pneumococcal pneumonia is rarely found as a complication of chronic pulmonary tuberculosis

Postoperative pneumonia is a secondary condition due either to the aspiration of mucus and saliva into the air passages or to the irritating effect of the anesthetic on the bronchial mucous membrane Many of these cases should not be classed as postoperative pneumonia but as postoperative atelectasis Pneumococci of the less virulent types are usually isolated from the sputum These postoperative pulmonary conditions usually run a mild and atypical course

The *tubercle bacillus* is capable of producing a lobar type of consolidation Lobar pneumonia of tuberculous origin may run a course quite similar clinically to that of pneumococcus pneumonia In the majority of instances however tuberculous pneumonia terminates fatally

Diagnosis —In a typical case of pneumonia the diagnosis can usually be made within a few hours after onset although the characteristic physical signs may not have made their appearance A patient suddenly taken with chill followed by fever herpes cough dyspnea and pain in the side presents a picture which can hardly be mistaken for any other condition There are a certain number of cases however usually secondary to some mild respiratory infection in which the onset is gradual and in which the more characteristic symptoms may be entirely absent Lobar pneumonia may develop without chill or pain in the side even the cough and expectoration are sometimes absent In cases of this type rapid respiration associated with cyanosis is a suggestive combination of symptoms As has been stated before the respiratory rate in pneumonia is nearly always out of proportion to the degree of fever One of the most convincing evidences of lobar pneumonia is the typical rusty sputum which is practically never seen in any other condition

It is important for the student of medicine to recognize the early symptoms and signs of pneumonia in order that specific treatment may be applied promptly Slight dulness a few moist rales and diminished breath sounds may be the only local signs during the first twenty four or thirty six hours of the disease Of these signs suppressed breathing is perhaps the most important By the third day frank signs of consolidation are usually present—increased vocal fremitus dulness and bronchial voice and breathing

The diagnosis of bronchopneumonia often presents a more difficult problem than that of lobar pneumonia for the clinical picture may be less typical As a rule the diagnosis of bronchopneumonia may be safely made when the temperature and respiration rate

two instances of this complication in the writer's experience have both occurred during convalescence

Pneumococcus peritonitis was seen in only three of the Bellevue cases All three patients died

Pneumococcus abscesses of the skin are occasionally observed but usually skin infections encountered in pneumonia are of staphylococcal origin

Associated Conditions—In addition to the above described pneumococcus complications there are a number of other conditions frequently seen in association with lobar pneumonia

Lung abscess is not so common a sequel of lobar pneumonia as is generally supposed When present, it is usually due to bacteria other than the pneumococcus—in most cases, to staphylococci and the fusospirochetal organisms In 2122 patients with Type I and Type II lobar pneumonia observed in the wards of Bellevue Hospital lung abscess occurred in only nine

Acute Nephritis—Many patients show signs of renal irritation, such as the presence of albumin and casts in the urine, but genuine nephritis is a rare complication

Parotitis occurred in seven of the Type I and Type II Bellevue cases and in those where cultures were taken the infection was of staphylococcal origin Osler says that parotitis is commonly seen in association with endocarditis where it is presumably a pneumococcus infection This does not agree with our experience though it has usually occurred in severe types of pneumonia The death rate in the Bellevue cases was 70 per cent In our series drainage by massage gave better results than surgical intervention

Otitis Media is the most frequent complication of pneumonia in children This condition is usually not a serious one and appears rather as an incident in the course of the disease Otitis media rarely occurs in adult pneumonia

Atelectasis of one or more lobes of the lung due to obstruction of a main bronchus with sputum or mucus is sometimes revealed by x ray or fluoroscopic examination Radiographs show the diaphragm to be elevated and the mediastinum retracted toward the collapsed lung When this condition occurs coincidentally with pneumonia it is serious when it occurs after the infection has subsided as is most frequently the case it merely retards convalescence Special treatment for this complication is usually unnecessary although in some cases bronchoscopic removal of the plug from the bronchus may give spectacular results

Unresolved Pneumonia—Delayed resolution is a sequel of pneumonia which may occur at any age, but is seen chiefly in elderly patients In the average case of pneumonia the signs in the lungs usually clear up completely within a week or ten days after crisis In the Johns Hopkins series of Osler 3 to 4 per cent of patients showed delayed resolution In most cases the signs persist for two or three weeks but in some instances they continue for several months During this period the temperature is normal, or only slightly elevated The patient has no particular discomfort but the strength and weight do not return to normal Physical examination usually shows bronchial breathing associated with moist rales but sometimes the bronchial breathing disappears and only the dulness and rales persist

Chronic Interstitial Pneumonia—Occasionally a patient with delayed resolution fails to recover and the condition passes into a chronic interstitial pneumonia the symptoms of which are described elsewhere

Relapse and Recurrence—Relapse is not common in pneumonia Subsequent to the first attack the temperature may remain normal from one to ten days or even two weeks Relapses in pneumonia are usually but not always caused by a type of pneumococcus different from that of the first attack The severity of the relapse naturally depends on the character of the second infection Relapses are usually seen in hospital wards where the new infection is picked up from some neighboring patient *Streptococcus haemolyticus* pneumonia secondary to pneumococcus pneumonia was frequently observed during World War I We have seen a number of relapses in patients who had received inadequate doses of serum or sulfonamide therapy

Recurrence is more frequently observed in pneumonia than in any other acute infectious disease By reason of this fact the impression prevails that one attack actually

it is intensified In pneumonia the voice and breath sounds are loud and tubular, in pleural effusion they are diminished In children however pleural effusion may present nearly all the signs of a pneumonic consolidation It must not be forgotten that pneumonia and pleurisy may coexist

Tuberculous pneumonia may closely resemble lobar or bronchopneumonia of pneumococcal origin in the character of the onset symptoms and physical signs and in many cases it is impossible to distinguish between the two conditions until a week or two has elapsed The history of pre-existing tuberculosis or involvement of the upper lobes suggests tuberculous pneumonia A high leukocyte count may be seen in both conditions Sooner or later the patient expectorates large quantities of purulent sputum in which tubercle bacilli can readily be demonstrated

Pulmonary infarction may simulate lobar pneumonia especially when the infarct is of considerable size In patients with chronic cardiac disease the diagnosis of lobar pneumonia should never be made until pulmonary infarction has been excluded The latter condition is not so apt to be ushered in with a chill the fever is not so high and there is not so much change in the leukocyte count In pulmonary infarction the sputum is bloody rather than rusty Pulmonary infarcts sometimes become infected and develop into frank pneumonic processes

Lung Abscess—In its early stages lung abscess may be indistinguishable from pneumonia When an abscess ruptures into a bronchus the sputum is usually profuse and of foul odor A history of aspiration of a foreign body or of a recent operation on the upper respiratory tract points to an abscess An x ray of the chest will usually settle the point but not always A week or ten days may elapse before the abscess takes on its characteristic clinical picture

Pneumonia is sometimes mistaken for *appendicitis* and *cholecystitis* in cases where diaphragmatic pleurisy is present In such cases the pain is referred to the abdomen and there may be considerable abdominal tenderness and rigidity

Prognosis—The fatality rate in pneumonia depends upon a great many factors In the large city hospitals of both Europe and America the mortality rate is usually in the neighborhood of 30 per cent In Bellevue Hospital the records show that the death rate has varied considerably from year to year ranging from 30 to almost 50 per cent In recent years the fatality rate has been dropping rapidly, due largely to the introduction of sulfonamide therapy

The fatality rate in private practice is distinctly lower than that in hospitals This is due of course to the fact that mild cases are treated at home while severe ones are sent to hospitals

Age of Patient—Youth is the greatest of all assets in pneumonia In children between two and ten years old the death rate is less than 10 per cent and the figure is no higher for patients in the second decade of life In hospital practice the mortality rate tallies closely with the age of the patient that is 20 per cent between the ages of twenty and thirty 30 per cent between thirty and forty and so on Comparatively few patients more than seventy survive the disease The fatality rate for bronchopneumonia in infants less than two years of age has always been high This however like the fatality rate for other age groups is being greatly reduced by sulfonamide therapy

Type of Infection—The prognosis in lobar pneumonia is definitely related to the type of pneumococcus responsible for the infection In the accompanying table the death rate for the various types has been determined by compiling figures from the reports of various writers including our own studies at Bellevue Hospital It will be noted that the three most prevalent types of pneumonia (Types I II and III) have the highest death rates The high death rate for Type III pneumonia can be attributed in large part to the high incidence of Type III pneumonia in elderly people Type III pneumonia in young people is not especially malignant The less prevalent types are distinctly milder in character The figures in the table below do not include any cases treated with serum or sulfonamides

Extent of Infection—The prognosis in lobar pneumonia is much less serious when the infection is confined to one lobe In our cases the death rate in one-lobe infections was only 20 9 per cent while that for multilobar infections was 40 per cent

are increased and localized rales are heard in the lungs The insidious onset of bronchopneumonia, its secondary character remittent type of fever, the fine moist rales and the absence of high pitched tubular breathing are important differential points in distinguishing it from lobar pneumonia

The laboratory aids in the diagnosis of pneumonia are (1) typing of the sputum, (2) blood culture (3) leukocyte count (4) x ray examination The first three of these are indispensable to the proper handling of the case X ray examination is of great help in certain cases but is not necessary as a routine procedure Sputum typing should be are taken under sterile precautions and transferred to a suitable blood culture medium usually plain beef extract broth If possible, it is well to plate out 1 or 2 cc of the blood with agar, in order to determine the number of colonies of pneumococci per cubic centimeter of blood

Differential Diagnosis—*Influenza* and *acute bronchitis* may be easily confused with a mild pneumonia, particularly at the outset Either one may start with a chill They are characterized by fever muscular aching and cough However, the sputum is not rusty and pleural pain is almost never seen The physical examination of the chest will

Fig 15—G D age forty three years Lobar pneumonia pneumococcus Type II X ray shows consolidation of right lower and lower portion of right upper lobe

carried out as soon as the clinical diagnosis of lobar pneumonia has been made In upper lobe infections the physician should always eliminate the possibility of a tuberculous lobar pneumonia by examination of the sputum for tubercle bacilli Blood culture is of valuable aid in the diagnosis and prognosis of pneumonia It is the best check on the sputum typing It is the best index to prognosis as patients with positive blood cultures have a fatality rate four times higher than patients with negative blood cultures A positive blood culture by reason of its serious import is an indication for intensive specific therapy Five cc of blood be negative except for occasional sibilant or sonorous rales The leukocyte count is normal or only slightly elevated In case of doubt an x ray of the chest should settle the question

Pleurisy is often confused with pneumonia especially when there is pleural effusion In both pneumonia and pleurisy the affected side shows some degree of immobility and there is dulness on percussion but in pneumonia the intercostal spaces are not obliterated the heart is rarely displaced and the dulness is not absolute Most important of all vocal fremitus is decreased or absent in pleurisy with effusion while in pneumonia

to relieve the pain but to give the patient rest and sleep The former prejudice against the use of morphine in pneumonia was probably not justified Most modern writers on the subject look upon morphine as perhaps the most important remedy at hand for con trolling pain restlessness delirium and other untoward symptoms It is contraindi cated however in patients showing an ex cess of moisture in the lungs Cough is often a troublesome symptom and like pain is best controlled by codeine or morphine Some practitioners advocate ammonium chloride or ipecac as an expectorant when the cough is dry Restlessness and insomnia may be relieved with sodium bromide phenobarbital or some of the other barbiturates If the pa tient becomes actively delirious paraldehyde or morphine is preferable Abdominal dis tention is encountered in nearly every severe case of pneumonia It must be attacked promptly in order to remove the extra burden which it places on the circulation and respiration In many cases proper at tention to the bowels will prevent distention Enemas are usually preferable to cathartics and a soapsuds enema is recommended once every twenty four hours When distention is marked the enemas should be supplemented by turpentine stupes and hypodermic in jections of surgical pituitrin in doses of 0.5 to 1 cc It is also advisable to insert a rub ber tube into the rectum preferably imme diately following an enema to facilitate the passage of gas Hyperpyrexia and the de lirium which often accompanies it may be relieved to some extent by sponge baths

Oxygen Administration —The rational method of treating cyanosis and dyspnea in pneumonia is by the administration of oxy gen It is known that the degree of cyanosis is usually inversely proportionate to the oxygen saturation of the arterial blood and further that in many cases the inhalation of 40 to 50 per cent oxygen raises the per centage of saturation to normal or nearly normal It has already been pointed out that many of the distressing symptoms of pneu monia and consequently the prognosis are closely related to the amount of anoxemia the relief of which is accompanied by definite beneficial effects Within two or three hours after the treatment is instituted the cy anosis disappears or greatly diminishes the patient becomes quiet and more comfortable (frequently sleeping for the first time in many hours) respiration is slower and deeper the pulse is decreased sometimes the temperature drops a degree or two A change in mental state is frequently observed This symptomatic relief, which frequently occurs demonstrates the value of oxygen In some cases oxygen therapy seems to prolong life until the patient develops an immunity against the infection and for this reason it is believed to be a life saving measure

At the present time there are four satis factory methods of administering oxygen They are (1) the *nasal catheter* or *metal cannula* in combination with a high pressure oxygen supply and a reducing valve (2) the *portable oxygen tent* (3) the *oxygen chamber* and (4) the *oxygen mask* or *hood* Each method has its advantages and dis advantages

The *nasal catheter* is the simplest the most economical and the most readily avail able The catheter should be of small size lubricated with petrolatum and perforated at the end by five or six small holes so that the stream of oxygen is not continu ously directed against a small area of the mucous membrane The tip of the catheter should be withdrawn about ½ inch from the nasopharynx to prevent irritation and the outer portion securely fastened to the side of the cheek or forehead with adhesive tape When four to five liters of oxygen per min ute is administered through the catheter a concentration of 35 to 37 per cent is obtained in the inspired air which is often sufficient to give symptomatic relief When the nasal catheter is inserted through the nostril and down the posterior wall of the larynx to a point opposite the glottis or the uvula the oxygen concentration of inspired air is higher by at least 5 per cent than when the catheter is placed in the nasopharynx Thus 5 liters of oxygen per minute will give an oxygen concentration of 45 per cent in the inspired air and 7 liters of oxygen per minute will provide an oxygen concentration above 50 per cent With proper care in the placement of the catheter in the oropharynx barely short of the point at which swallowing the gas occurs during deglutition relatively high concentrations of oxygen can be maintained in the inspired atmosphere

FATALITY RATE FOR FIRST EIGHT TYPES OF PNEUMOCOCCAL PNEUMONIAS*

Types	Cases	Deaths	Per cent
I	762	288	37 7
II	557	258	46 3
III	999	474	47 4
IV	166	42	25.3
V	254	73	28 8
VI	68	18	26 4
VII	227	50	22 0
VIII	295	55	18 6

None received serum or sulfonamides

BACTEREMIA —This complication may occur in pneumonia of any type and renders the prognosis much more serious At Bellevue Hospital the death rate in Type I pneumonia with bacteremia was 66 7 per cent in Type II septic cases it was 87.5 per cent The corresponding figures for patients whose blood remained sterile were 22 per cent for Type I, and only 8 5 per cent for Type II Septicemia is so commonly associated with fatal lobar pneumonia that a patient s chances for recovery might almost be said to depend on the prevention or relief of this condition Not only is the fatality rate related to the presence or absence of bacteremia but it is also dependent in great measure upon the number of organisms present in the blood stream For example in a large series of Type II patients receiving no specific treatment there were only three with more than five organisms per cubic centimeter of blood who recovered

Other Factors in Prognosis—RACE and SEX appear to have very little influence on the death rate of pneumonia It has been claimed that the death rate is higher in the Negro than in the white race but these figures have been questioned

HABITS —It is needless to say that a patient s habits play an important part in prognosis In the writer s series the death rate from pneumonia in alcoholics was 56 per cent almost twice as high as that for the cases in which alcoholism was not a factor Patients in good physical condition have a much better chance than those who have been exhausted or worn out by some previous illness or by overwork Correspondingly the patient s station in life is significant Patients in the higher walks of life being well fed and clothed and usually in good physical condition are a better risk than those who are poor underfed and ill clothed

Treatment —The treatment of pneumonia is governed by the general principles that apply to the treatment of all acute infectious diseases The treatment is concerned with (1) general care of the patient, (2) relief of distressing symptoms and (3) measures for overcoming the infectious agent

General Care of the Patient—The first essential in the proper care of a patient with pneumonia is good nursing There is probably no disease in which the services of a competent well trained nurse are more valuable The patient must be kept quiet and as comfortable as possible Everything should be done to encourage relaxation and sleep and to keep up the patient s morale The sick room should be properly ventilated but the patient must be kept warm and well protected from drafts During the acute stage, the patient should be forced to take plenty of fluid particularly water, although such beverages as weak tea, ginger ale Vichy or other waters are sometimes more palatable to the patient and should be allowed As much as three liters of fluid should be given in the twenty four hour period The diet does not play as important a part in the treatment of pneumonia as in certain other infections The disease usually runs a short course so that a high caloric intake during the acute period is not required indeed in some instances it may harm the patient by causing distention A liquid diet is usually preferable the basis of which should be milk cream broth and fruit juices

Symptomatic Treatment—In the mild infections the treatment of symptoms may be entirely unnecessary but in severe cases it becomes one of the physician's most important duties How to relieve the pleuritic pain is one of the first problems that arise Occasionally the pain is alleviated by counterirritation in the form of an ice bag hot poultice or mustard plaster A chest binder is preferable to adhesive plaster for immobilizing the chest Codeine 0 03 to 0 06 Gm (½ to 1 grain) by mouth is often helpful but in cases where the pain is very severe morphine in small doses 0 008 to 0 01 Gm (⅛ to ⅙ grain) hypodermically should be used without hesitation not only

by Whitby in 1938, when he showed its remarkable protective power in mice against various types of virulent pneumococci

Soon after publication of Whitby s experiments a clinical report was made by Evans and Gaisford on the effect of the drug on pneumonia in man These writers noted a fatality rate of only 8 per cent in their 100 cases of pneumococcal pneumonia treated with sulfapyridine while the control group of untreated cases showed a death rate of 27 per cent It was soon discovered however that sulfapyridine though possessing remarkable value in controlling pneumonia had certain practical disadvantages Its ingestion caused intense nausea and vomiting in a considerable proportion of patients and produced other toxic effects which soon led to a search for a less objectionable agent

Sulfathiazole another sulfonamide derivative was introduced in 1939 and it soon became evident that it possessed definite advantages over sulfapyridine Only 25 per cent of patients receiving sulfathiazole became nauseated and the degree of conjugation of the drug in the blood and urine was much less than that which occurred with sulfapyridine As a result a larger proportion of the drug absorbed into the blood stream was therapeutically active Numerous clinical reports have indicated that from the therapeutic standpoint sulfathiazole is equally as efficient as sulfapyridine in controlling pneumococcal infections

In 1940 sulfadiazine another sulfonamide derivative was introduced by Roblin and his co workers Laboratory studies indicated that sulfadiazine had even less toxicity than sulfathiazole and sulfapyridine and was equally as effective against experimental pneumococcal infections At the present time sulfadiazine is the most popular of the sulfonamide drugs for the treatment of pneumonia although for economic reasons sulfathiazole is still being widely used It is now universally conceded that the results obtained by these three forms of sulfonamide therapy are about equally good the prompt administration of any one of the three will reduce the usual pneumonia death rate of 30 per cent to approximately 6 or 7 per cent In the case of all three drugs a considerable inactive fraction accumulates in the blood in the form of conjugated or acetylated salt Due to this fact it is impossible to foretell from the amount of the drug administered the actual blood level of the active unbound drug It may vary widely due to the difference in the amount of drug conjugation in different subjects The ideal blood level of free drug has not yet been established but it is probably somewhere between 6 and 12 mg per 100 cc of blood

The conjugated acetylated form is entirely useless so far as having any effect on the pneumococcus is concerned and furthermore it has the disadvantage of being so insoluble that it tends to precipitate in the kidneys ureters and bladder of animals which have received the drug Not infrequently the acetylated salt is demonstrable in the urinary tract of human subjects Blood determinations should be made at frequent intervals during the administration of the drug to be sure that an adequate blood concentration has been reached The methods of either Marshall or Werner may be used for this purpose

Sulfadiazine being the drug of choice the remainder of this discussion on sulfonamide therapy will be confined to sulfadiazine except where otherwise indicated It should be added that the use of sulfapyridine has now been almost completely discontinued because of its toxic effects

Outline of Sulfadiazine Therapy — The initial dose of sulfadiazine should be 2 to 4 Gm (30 to 60 grains) by mouth followed by 1 Gm (15 grains) every four hours day and night until the infection is well under control It is customary to continue this dosage for 24 to 72 hours after the temperature has reached normal The drug can then be discontinued or cut to half the previous dose or the regular dose can be continued every six to eight hours instead of every four hours After twenty four hours of half doses it is usually safe to discontinue the drug altogether In severe infections with bacteremia or extensive bilateral involvement it is advisable to continue full doses of sulfadiazine for five to six days after the temperature reaches normal

During the course of sulfadiazine therapy the urine of the patient should be kept alkaline by adequate doses of *sodium bicarbonate* This is a new and important phase of sulfadiazine therapy It has been shown that

In recent years, *oxygen tents* have been greatly improved The canopy has been increased in size and is now obtainable in transparent pliofilm which adds greatly to the comfort of the patient and also permits the physician and nurse to have a clear view of the interior of the tent

High concentrations of oxygen from 50 to 100 per cent may be administered by either the B L B or the O E M meter *mask* In the former a small rubber bag serves as a rebreathing bag and sponge rubber discs are employed as combination inspiratory and expiratory valves This mask is best employed with high flows of oxygen in order to overcome the resistance created by the sponge rubber disc and to prevent excessive accumulation of carbon dioxide which would otherwise be found in flows of oxygen from 3 to 4 liters per minute In the meter mask an injector is used which mixes oxygen with air before entrance to the mask and *supplies in an accurate way the prescribed* concentration of oxygen (40 to 100 per cent) in the inspired air No rebreathing occurs with the meter mask since a delicate inspiratory valve is placed in front of the latex bag which serves as a collecting container for the inspired oxygen The minimal resistance in this mask makes it possible to use it with low flows of oxygen Low oxygen flows from 3 to 4 liters per minute may be employed in this mask to yield concentrations of 40 and 50 per cent oxygen without accumulation of carbon dioxide Although mask oxygen therapy may be effectively employed in many patients with pneumonia there are others in whom continuous appliance to the face is followed by discomfort Under these circumstances the administration of oxygen could be continued with an oxygen tent if it is available or with a nasal catheter The special advantages of either the B L B or meter mask are that very high oxygen concentrations from 50 to 100 per cent may be administered when indications for it are present such as peripheral circulatory shock or edema of the lungs

In certain severe cases of pneumonia that are complicated by pulmonary edema the oxygen mask metered for positive water pressure may be indicated In treating pulmonary edema it is customary to begin with high pressures such as 4 cm , and gradually *lower the pressure to 2 and 1 cm* of water From 40 to 100 per cent oxygen is employed The combination of helium and oxygen is also used in the treatment of certain cases of pulmonary edema For this the helium oxygen hood is employed at first with a relatively high pressure of from 5 to 6 cm. of water then with pressures gradually reduced to 1 cm and finally to atmospheric pressure

Stimulation —The circulation of the patient must be watched for the first indication of failure *Heart failure per se* is much less common in pneumonia than has been supposed In a majority of fatal cases death is referable to either respiratory failure or vasomotor paralysis The latter is indicated by a low blood pressure, rapid thready pulse profuse perspiration and other symptoms of shock This is best treated with epinephrine, in doses of 0.5 to 1 cc which may *be given every twenty minutes for 6 doses* or until the blood pressure and pulse improve Caffeine may be used instead of epinephrine, or may be alternated with it Alcohol as a stimulant still has its advocates but the consensus seems to be that it should be administered only to patients who are chronic alcohol addicts Intravenous glucose or glucose and saline solutions have been used in recent years to produce an elevation of the blood pressure Care should be taken however not to overtax the right side of the heart by giving too much fluid by vein as *in some instances a rapidly progressive* pulmonary congestion and edema result In the hands of the writer this method of stimulation has been disappointing It is no longer considered good practice to administer digitalis as a routine in the treatment of pneumonia This drug is indicated only in cases which show definite signs of heart failure or for those patients who develop auricular fibrillation

Sulfonamide Therapy —The discovery of the sulfonamide drugs marks a revolution in the treatment of pneumococcal pneumonia The first of these drugs was sulfapyridine a derivative of sulfanilamide which differs from that drug in that one hydrogen atom of the sulfanilamide group is replaced by a basic pyridine group The first report on the therapeutic value of sulfapyridine was made

ministration Sodium sulfadiazine should be administered only by the intravenous route The drug is quite alkaline and necrosis may result if some of the fluid escapes into the subcutaneous tissue Usually 5 Gm in 100 cc of distilled water is given for an initial dose to the average adult When this dose is injected into the vein a free sulfadiazine level of 5 to 10 mg per 100 cc of blood is immediately established In order to maintain this effective level oral therapy with sulfadiazine should be started immediately after the intravenous injection If for various reasons oral therapy is not possible maintenance requirements must be provided by additional intravenous injections of sodium sulfadiazine In such case 2 Gm every eight hours is sufficient

The effect of sulfadiazine on the clinical course of pneumonia is usually prompt and dramatic Within a comparatively few hours after the initial dose the temperature may drop to normal by crisis and the patient seems much more comfortable With the drop in temperature there is a corresponding fall in pulse and respiration The drug however should not be discontinued at this point otherwise a relapse may follow As stated above the dosage may be cut to one half the previous amount and continued at four hour intervals for twenty four to seventy two hours after normal temperature and pulse rate have been obtained Administration of sulfadiazine by rectum has been tried in patients who cannot tolerate the drug by mouth but absorption by this route is slow and the clinical results are unsatisfactory

The Toxic Effects of Sulfonamides—The toxic effects of sulfonamides are varied Sulfathiazole and sulfadiazine are both less toxic than sulfapyridine However all three of these drugs can produce serious and even fatal reactions The patient must therefore be closely watched for toxic manifestations while sulfonamide therapy is being administered Similar toxic manifestations occur with all three drugs but are observed less frequently with sulfadiazine than with either sulfapyridine or sulfathiazole

The TOXIC SYMPTOMS which may follow the use of sulfadiazine are as follows NAUSEA and VOMITING are rarely seen so rarely that the question will usually be raised as to whether the symptoms are caused by the drug or by the infection

LEUKOPENIA is also a rare occurrence The leukopenia which exists before sulfadiazine is started is not a contraindication to its use When leukopenia develops during the course of treatment however it is usually wise to discontinue the drug at once A few cases of true agranulocytosis and several cases of purpura hemorrhagica have been reported

ANEMIA AND HEPATITIS—The severe hemolytic anemia which was seen occasionally during the use of sulfanilamide and sulfapyridine has been rarely observed with sulfathiazole or sulfadiazine Toxic jaundice is occasionally encountered

DRUG FEVER is often accompanied by dermatitis and occasionally by episcleritis The temperature is usually of low grade and subsides quickly after the drug is withdrawn The rash may be maculopapular scarlatiniform or morbilliform

NERVOUS and MENTAL MANIFESTATIONS occasionally psychoses have been reported following use of the sulfonamides This was more noticeable with sulfapyridine than it has been with sulfathiazole or sulfadiazine The symptoms most frequently reported have been marked mental depression delirium and disorientation Occasional instances of peripheral neuritis have been observed

COMPLICATIONS IN THE URINARY TRACT—Renal complications are the most frequent of the untoward manifestations of sulfadiazine therapy There is every reason to believe however that the urinary complications can be largely avoided by the forcing of fluids and the alkalinization of the urine The crystals of sulfathiazole and sulfadiazine are frequently found in the urine of patients who are receiving these drugs Usually they cause no unpleasant symptoms As a rule the crystals appear only after the urine has been allowed to stand at room temperature for several hours Macroscopic hematuria occurs in 1 to 2 per cent of patients Hematuria is nearly always associated with crystalluria Hematuria may or may not be accompanied by sharp pains in the costovertebral angles When because of insufficient fluid intake large quantities of crystals are precipitated in the tubules or around

the solubility of sulfadiazine is greatly increased in the alkaline urine and because of this fact *crystalluria* and the dangerous sequelae which often result from it can be avoided by maintaining the urine at a *p*H of at least 7.5

Gilligan Garb and Plummer advise 6 Gm (90 grains) of sodium bicarbonate as an initial dose to be administered by mouth with the first dose of sulfadiazine This should be followed by 2 6 Gm (40 grains) of the alkali every four hours with each Gm of sulfadiazine The total twenty four hour dose of bicarbonate would therefore be 15 6 Gm The alkali therapy should be continued for twenty four hours following cessation of sulfadiazine therapy

As the incidence of crystalluria is particularly high when sodium sulfadiazine is administered intravenously sodium lactate by vein should be given if the patient is unable to take alkali by mouth Sodium lactate or sodium citrate by mouth may be preferred by some patients in whom sodium bicarbonate causes nausea or other unpleasant symptoms The oral dosage of sodium lactate is one third greater, and that of sodium citrate one fifth greater than that of sodium bicarbonate The daily urinary volume of patients on sulfadiazine therapy should be 1500 to 2500 cc

If the patient does not react favorably to sulfadiazine, the blood should immediately be tested for its sulfadiazine level If this is very low steps should immediatel be taken to increase the blood concentratio either by increasing the amount of sulfadiazine by mouth or by giving sodium sulfadiazine intravenously

Sodium sulfadiazine (or sodium sulfathiazole) is a soluble form of the drug which i intended for emergency intravenous use It is available either as a white powder or in a 20 per cent aqueous solution It is readily soluble in distilled water and should be well diluted preferably to 5 per cent before ad

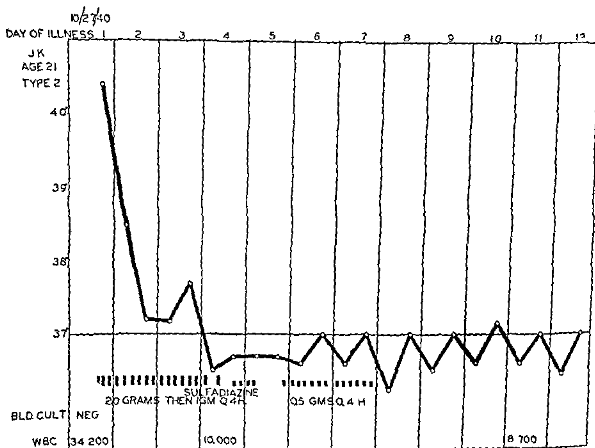

Fig 16—Temperature chart of a patient with Type II pneumonia treated with sulfadiazine during the first twenty four hours of his illness Initial dose 2 Gm., then 1 Gm every four hours until the temperature reached normal (Courtesy of Dr Norman Plummer)

of the disease In many instances a rapid drop of temperature occurs shortly after the injection and is accompanied by a corresponding drop in the pulse and respiration rate Cecil and Blake showed that monkeys affected with fatal Type I pneumonia could in every instance be saved by the intravenous injection of Type I antipneumococcus serum In these experiments the serum not only lowered the temperature but quickly cleared the blood of pneumococci

In recent years antipneumococcus serum has been gradually refined and concentrated so that the modern product is many times more potent than the original Furthermore because of the reduced protein content the refined serum is much less prone to cause reactions in the patient

The following table compiled from various sources gives the results of serum therapy for the more prevalent types of pneumonia

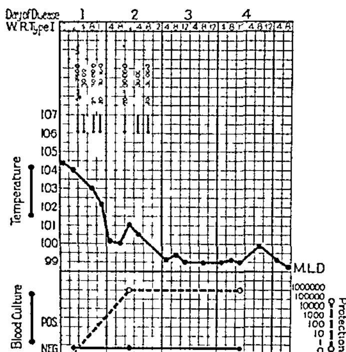

Fig 17.—Pneumococcus Type I pneumonia. Treatment with Type I concentrated serum on the first and second days of the disease The broken line below indicates the appearance of immune bodies in the patient's blood after the injection of serum

Fatality Rates for Pneumococcus Pneumonia of the Commoner Types, with and without Serum

Type	*Serum Treated*			*No Serum*		
	Cases	*Deaths*	*Per cent*	*Cases*	*Deaths*	*Per cent*
I	3136	429	13 6	558	182	32 6
II	964	302	31.3	967	424	43.8
IV	139	35	25 1	516	187	36.2
VII	109	13	11 9	404	117	28.9
VIII	41	4	9.8	319	60	18.8
XIV	39	4	10 2	167	34	20.3
Total	4428	787	17 7	*2931	1004	34.2

The one exception to these satisfactory results with serum has been in the case of Type III pneumonia in which Type III antipneumococcus serum has yielded rather disappointing results

It will be seen from these figures that the death rate is cut approximately one half by serum therapy The reduction however is more marked when only patients treated early are included

the calices concretions and actual calculi may form in the pelves of the kidney These may produce gross hematuria and sharp pain in the costovertebral angles, and if a stone or gravel engages the ureter, typical renal colic may ensue Sharp increase in the level of nonprotein nitrogen of the blood has been noted in a small percentage of cases Occasionally when crystalluria is marked there may be a pronounced reduction in the urinary output or even complete urinary suppression In such cases the urine becomes very scanty and of a smoky appearance, and contains large numbers of crystals and red blood cells A number of fatalities have been reported in such cases The urinary complications described above can be avoided by careful supervision of sulfonamide therapy Fluids should always be forced to amounts of 3 or 4 liters daily, and if oliguria develops the fluid intake should be increased promptly, and the drug discontinued If there is marked or complete suppression of the urine, particularly when accompanied by ureteral pain fluids should be forced by mouth and parenterally and ureteral catheterization should be employed early if a fatal outcome is to be avoided

Recent studies have indicated that if the alkalinity of the urine is maintained by administration of adequate amounts of alkali precipitation of sulfonamide crystals does not take place in the urinary tract This is an important contribution to sulfonamide therapy and should go far toward eliminating serious urinary complications

Because of the occasional development of blood and renal complications every patient who is receiving sulfonamide therapy should have a routine blood count and urinalysis every forty eight hours during the period of drug administration

Two new sulfonamide derivatives have recently been introduced by English investigators sulfamethazine and sulfamerizine Both products apparently possess bacteriostatic power over the pneumococcus and streptococcus similar to that observed in the case of sulfathiazole and sulfadiazine At the present time therapeutic investigation of these new drugs is being conducted in several American hospitals However they have not yet received sufficient study to justify their use in practice

Acquired Hypersensitivity to Sulfonamides —Bullowa and others have reported instances of acquired hypersensitivity to the various sulfonamides where they have been administered repeatedly to the same patient Two such cases have come under the observation of the writer In such patients the first administration of the drug has caused no unpleasant symptoms In some cases this sensitization to one of the sulfonamides holds also for its closely related derivatives Hypersensitivity to sulfonamides manifests itself by the prompt appearance of fever skin rash and systemic reactions The rash is morbilliform or urticarial and is occasionally accompanied by swellings of an angioneurotic character The rash is characterized by intense itching

Serum Therapy—Before the advent of sulfonamides, the only specific treatment for pneumonia was serum therapy After many years of experimentation the serum therapy of pneumonia had been developed to a point of efficiency where it was capable when properly used of cutting the death rate for the various types to approximately half that for untreated cases Within a year however after the introduction of sulfonamide therapy it became apparent that sulfonamide therapy was much simpler and more effective than serum therapy Serum therapy is still used in certain selected cases A brief discussion therefore of serum therapy seems desirable

Antipneumococcus serum was first prepared against pneumococcus Type I pneumonia by immunizing horses against Type I cultures and using their serum intravenously in patients with Type I pneumonia The first reports on the value of Type I serum were made by Cole and his co workers at the Rockefeller Institute In a series of 431 cases the fatality rate was 10 2 per cent as compared with the usual rate of 30 per cent for cases not receiving serum Since the original studies of Cole the value of Type I serum has been widely corroborated in all parts of the world and in recent years specific serums have been introduced for the other types of pneumonia

The clinical effect of specific serum on a patient with pneumococcus pneumonia is often dramatic particularly if administered in the first twenty four to forty eight hours

102° F and often there is pain and swelling in various joints These symptoms persist for a few days and then disappear

Contraindications to Serum Therapy —Serum therapy is contraindicated (1) in all cases of pneumonia where the type of pneumococcus cannot be determined (2) in patients who give a history of recent administration of serum (3) in severe asthmatics who are not considered good risks for serum therapy, (4) in the presence of a strongly positive skin or eye reaction to horse or rabbit serum.

Combined Sulfonamide and Serum Therapy—There has been considerable debate in the recent literature concerning the advisability of combining sulfonamide therapy with serum therapy in the presence of severe pneumonia *All are agreed that in the average* case sulfonamide therapy suffices However a certain number of pneumonia patients die in spite of sulfonamide therapy and it has been claimed that a percentage of these patients could be saved by a combination of serum with chemotherapy Plummer and his associates have recently published an extensive statistical study in which they conclude from carefully controlled figures that the fatality rate was not affected by the addition of serum to chemotherapy A final answer can not be given to this question at the present time In any case the present role of serum in pneumonia appears to be its use in the treatment of patients who cannot tolerate sulfonamides or who do not respond satisfactorily within twenty four to forty-eight hours to sulfonamide therapy Since the introduction of sulfonamides there has been a rapid and progressive fall each year in the amount of serum administered in both hospital and private practice

STREPTOCOCCUS HAEMOLYTICUS PNEUMONIA

Definition —*Streptococcus haemolyticus* pneumonia is usually classifiable as broncho pneumonia though at times it takes on the picture of lobar consolidation

Incidence —The *hemolytic streptococcus*

It should be stressed that serum therapy is highly specific for type and therefore requires careful bacteriologic control Serum should always be given intravenously and in adequate doses In most cases an uncomplicated pneumonia in a person twenty five to thirty years of age responds with rapid crisis to the introduction of 50 000 to 100-000 units of serum These doses are probably sufficient for types other than Type II, which generally requires 100 000 to 200 000 units for uncomplicated cases The required dosage increases with age with delay in treatment in patients who are pregnant or whose blood cultures reveal a bacteremia and in those cases with extensive involvement In the last few years antipneumococcus rabbit serum has been introduced as a substitute for horse serum over which it has certain theoretical and practical advantages

The patient is first questioned as to previous injections of horse or rabbit serum as well as to a history of hay fever asthma or other allergic phenomena Conjunctival and skin tests are next made with a 1 10 dilution of serum and if after fifteen minutes these tests are negative 1 0 cc of serum is slowly injected intravenously The patient should be carefully watched for increase of dyspnea cyanosis flushing of the face and for the appearance of urticaria If any of the signs of a reaction occur the needle should be withdrawn immediately and 0 5 cc of epinephrine injected subcutaneously Epinephrine may be repeated two or three times if the reaction increases After the first injection of serum there is very little danger of reaction so that larger amounts can be safely administered A second injection of 15 to 20 cc is given intravenously from one to two hours later and this dose is repeated every two or three hours until the patient has received about 100 000 units of serum The amount of serum administered on the following day is determined by the clinical condition of the patient If as often happens the patient s temperature drops to normal no further serum therapy may be necessary If on the other hand the patient s condition is worse or if it remains unchanged intensive treatment is continued On the third day the same policy is pursued It has been found that if any benefit is to result from serum treatment it is usually apparent after two or three days of treatment

At the present time there is a tendency in some institutions to give the entire therapeutic dose of serum in one injection This may be achieved by direct intravenous injection of serum with a large Luer syringe or better still by making use of an intravenous infusion set diluting the serum with 500 cc of sterile physiologic salt solution and allowing the mixture to enter the vein very slowly by gravity This method of administering serum probably gives a more brilliant therapeutic effect but should be employed only by those thoroughly familiar with serum therapy In ordinary circumstances it would seem safer to divide the therapeutic dose into two or three injections of 25 000 to 50 000 units each

SERUM REACTIONS —The injection of serum may be followed by several types of reactions (1) the allergic reaction, (2) the thermal reaction, (3) serum sickness

(1) *The Allergic Reaction* —When individuals are highly sensitive to horse or rabbit serum symptoms of shock may appear a few minutes after the introduction of serum The patient suddenly becomes dyspneic, there is flushing of the face and asthmatic breathing followed by sweating urticaria and general anxiety The symptoms can usually be relieved by the prompt hypodermic injection of 0 5 to 1 cc of epinephrine 1 1000 solution Shocks of this kind may end fatally but this seldom happens except in cases where proper precautions have not been taken

(2) *Thermal Reaction* —Sometimes the injection of antipneumococcus serum is followed by a foreign protein reaction which is quite different in character from the allergic one Thirty to sixty minutes after the injection of serum the patient has a chill which is followed by a rapid rise in temperature The temperature remains high for several hours then there is a rapid drop accompanied by profuse perspiration

(3) *Serum Sickness* —The severity of serum sickness depends in part on the amount of serum protein injected Symptoms usually appear seven to fourteen days after the injection of serum though they may come earlier The patient breaks out in a profuse urticaria the temperature rises to 101° or

not reduce the incidence of empyema Cases that develop empyema usually require surgical intervention and thoracotomy, though a certain number will recover following multiple aspirations of the chest In the last war it was found that better results were obtained when thoracotomy was postponed until the pleural fluid took on a frankly purulent quality Antistreptococcus serum has been advocated but is less efficient than sulfonamide therapy

STAPHYLOCOCCUS AUREUS PNEUMONIA

Staphylococcus aureus pneumonia is a comparatively rare form of pulmonary infection constituting about 1 per cent of all cases of pneumonia It is characterized by the bronchial type of consolidation suppurative bronchiolitis and multiple miliary abscesses A more complete description of *Staphylococcus aureus* pneumonia will be found in the chapter on *Staphylococcus aureus* Infections (p 164)

RUSSELL L CECIL

FRIEDLÄNDER S BACILLUS PNEUMONIA

At least 1 to 3 per cent of all cases of pneumonia are caused by the Friedlander s bacillus This micro-organism produces a characteristic lobar type of consolidation For a full description of Friedlander s bacillus pneumonia see Chapter on Friedlander s Bacillus Infections (p 314)

RUSSELL L CECIL

HEMOPHILUS INFLUENZAE PNEUMONIA

Hemophilus influenzae pneumonia is quite rare except in times of epidemics though the *H influenzae* is frequently found in association with other pathogenic organisms In such mixed infections the role of the *H influenzae* is difficult to determine though it probably enhances the virulence of the pneumococcus or streptococcus which accompanies it

Blake and Cecil produced experimental pneumonia in monkeys with pure cultures of *H influenzae* The characteristic features were a tracheobronchitis hemorrhagic edema of the lungs bronchiolitis and bronchopneumonia In man the pathologic changes are quite similar to those produced in monkeys There is a widespread injury to the mucosa and submucosa of the bronchi extending down into the bronchioles Its intensity may vary from a catarrhal inflammation to actual necrosis and destruction of the bronchial walls leading to acute bronchiectasis

The fatality rate of pure *H influenzae* pneumonia is difficult to determine because of its rarity and also because of the possibility that the infection was initiated by some other organisms or by a filtrable virus with the subsequent development of *H influenzae* pneumonia

The treatment of *H influenzae* pneumonia is symptomatic A few cases appear to have been favorably influenced by sulfonamide therapy but in others the use of the drug has been disappointing

VIRUS PNEUMONIAS

During the past few years an atypical form of pneumonia of unknown etiology has been reported with increasing frequency No pathogenic bacteria have been found in the sputum or in the bloodstream of these patients Even in those cases that come to autopsy no bacteria have been recovered from the consolidated lung tissue This type of pneumonia has been generally referred to as virus pneumonia However as these

is responsible for 3 to 5 per cent of all cases of pneumonia, though its frequency varies from time to time depending on predisposing factors and the presence of epidemics of respiratory infection which create favorable conditions for invasion of the organism

Epidemics of streptococcal pneumonia have occurred at various times particularly during great wars In times of peace, streptococcal pneumonia is much less fatal than in times of war, except in those cases where local epidemics occur

Etiology —Streptococcal pneumonia occurs most frequently during epidemics of *influenza* or *of measles* Less frequently streptococcal pneumonia is secondary to a common cold, streptococcal sore throat, scarlet fever or erysipelas Occasionally it acts as a secondary invader in pneumococcal pneumonia At other times however particularly in epidemics when the virulence of the organism is greatly increased streptococcal infection of the lungs may be primary, that is without any preceding illness

Morbid Anatomy —In the vast majority of cases the *Streptococcus haemolyticus* produces a pneumonia of the bronchial or lobular type The characteristic lesion varies from an interstitial pneumonia with peribronchial nodes to more extensive lobular consolidations with subpleural abscesses and interstitial suppurative pneumonia In monkeys with experimental pneumonia Blake and Cecil were able to duplicate these lesions and showed that the larger doses of organisms produced a more extensive lobular consolidation and tissue necrosis As in pneumococcal pneumonia the lower lobes on one or both sides are the ones most frequently involved

Symptoms and Signs —The symptoms vary with the severity of the infection The sporadic cases are prone to be mild with symptoms quite similar to those of pneumococcal bronchopneumonia The onset is usually gradual and follows influenza measles or some other preceding infection The temperature curve is of the irregular type and the signs in the chest are indefinite In the majority of cases small areas of dulness and moist rales comprise the positive physical findings

In epidemics of streptococcal pneumonia such as that which occurred during World War I, the clinical course takes on a more malignant character At such times the disease may be primary without any preceding infection The leading symptoms are severe intoxication the remittent type of fever cough with mucopurulent or bloody expectoration intense dyspnea and cyanosis and a tendency to early infection of the pleural cavity, with the development of empyema Pleural effusion is sometimes present within twenty four hours of the time of onset The pleural fluid is at first bloodstained and contains innumerable streptococci later it becomes frankly purulent The intrapulmonary process is frequently obscured by the effusion and the physical signs may be not unlike those of pneumococcal pneumonia the fluid transmitting the bronchial breathing quite distinctly The pneumonia is septic in type, especially in those cases in which streptococci invade the bloodstream and not infrequently results in the formation of pulmonary abscess Recovery is slow, with convalescence long drawn out, especially when the disease is complicated by empyema

Diagnosis —The diagnosis of streptococcal pneumonia is made from the examination of sputum The character of the pneumonia can be determined by x ray examination It is particularly important in following this type of pneumonia, to be on the lookout for empyema

Prognosis —In endemic cases the prognosis is excellent Lawrence and Sutliff found in analyzing a group of 81 cases that there were 10 deaths with a fatality rate of 12 3 per cent In a series recently reported by Keefer and his associates the death rate was 18 per cent These figures are in sharp contrast to those obtained in the epidemic of 1917–1918 when the fatality rate of epidemic streptococcal pneumonia ran as high as 50 to 60 per cent At the present time, of course the prognosis has been greatly improved by the introduction of sulfonamide therapy

Treatment —The treatment of streptococcal pneumonia differs in no essential respect from that of pneumococcal pneumonia Sulfonamide therapy is of great value particularly in those cases where it is administered early in the disease According to Keefer however sulfonamide therapy does

lent in various parts of the United States The onset was acute with headache chilly sensations, malaise and coryza Several patients developed a hacking cough which in a few cases was accompanied by tenacious white mucoid sputum Physical signs were quite meager, consisting chiefly of small areas of dulness and a few moist rales The pneumonia was best demonstrated by x rays which showed soft infiltrating lesions either single or multiple and tending to be patchy Since the epidemic of American Q fever in 1940 several other cases have been reported Only one of the fifteen cases in the Washington epidemic died

Primary Atypical (Virus) Pneumonia of Unknown Etiology —During the last two or three years there has been prevalent a peculiar form of bronchopneumonia usually referred to as virus pneumonia It differs from the virus pneumonia caused by known viruses in that no etiologic agent of any kind has as yet been recovered from the infected patient

Incidence —Virus pneumonia has been reported from all parts of the United States and England The disease occurs sporadically and in small outbursts The incidence in a report from Cornell University was approximately nine per one thousand students The vast majority of reported cases of virus pneumonia have occurred in adolescents and young adults in schools colleges and army camps The seasonal distribution is variable and sporadic Cases may occur at any season of the year

Etiology —The term virus pneumonia has been applied to this group of cases in a rather unscientific way as no virus has as yet been actually isolated The only justification for the use of the term is the absence of pathogenic bacteria from the sputum In all probability primary atypical virus pneumonia is not a disease but a syndrome which may be caused by a number of different agents In the absence of the usual pathogenic bacteria from the sputum and blood it seems most likely that a virus is responsible for most of them Pneumococci of the higher types have been found in a considerable number of the cases and to a less extent hemolytic staphylococci and streptococci may be demonstrable in certain instances However the clinical course the x ray findings and the failure of these patients to respond to sulfonamide therapy would indicate that these occasional pathogenic bacteria were probably accidental inhabitants and not actively concerned with the infection

Epidemiology —Virus pneumonia may be either epidemic or endemic in its manifestation However none of the epidemics have been very extensive or comparable to those of influenza Apparently the disease can be transmitted by contact but it is not highly contagious The high incidence of virus pneumonia in nurses and doctors suggests that the disease is often contracted by contact

Morbid Anatomy —Because of the low fatality rate, the morbid anatomy of virus pneumonia has not received thorough study However, in the few cases which have come to autopsy, the lungs have presented the picture of a patchy, hemorrhagic, interstitial bronchopneumonia accompanied by acute bronchitis and bronchiolitis The gross picture reveals small areas of consolidation which in places become confluent the bronchi are filled with mucoid or purulent exudate The picture is not unlike that of the influenzal pneumonia which was so prevalent during World War I Microscopically the alveolar septa show thickening and infiltration with mononuclear cells The process is most marked in the alveoli surrounding the bronchioles The walls of the bronchi and bronchioles show necrosis and infiltration with polymorphonuclear leukocytes and their lumens are filled with an acute inflammatory exudate Many of the alveoli contain edematous fluid and red blood cells

Symptoms —The incubation period is not known but apparently may be from one to twenty one days The infection makes its appearance with fever malaise headache chilliness and cough The temperature ranges from 99° to 105° F but is usually between 100° and 103° F The cough is one of the most characteristic and distressing features of the disease It is dry and occurs in paroxysms which are sometimes extremely difficult to control Substernal soreness and tenderness of the abdominal muscles often result from the continuous coughing As the disease progresses the cough may become produc

cases have been more carefully studied by bacteriologists it has become clear that they are not all caused by the same virus Finland and Dingle have recently reviewed the subject of virus pneumonia and they divide these infections into two main groups (1) pneumonias associated with known nonbacterial agents (2) primary atypical pneumonias of unknown etiology

Pneumonias Associated with Specific Viruses—Several of these are worthy of special mention

Influenzal Pneumonia—It is now generally accepted that a filtrable virus, probably identical with that demonstrated by Smith, Andrews and Laidlaw has been the exciting agent in most of the widespread epidemics of influenza that have occurred in the last few years This virus is referred to as Influenza A virus Another virus known as Influenza B virus can give rise to the same picture, and there is indirect evidence that still other varieties of influenza virus can produce the characteristic clinical picture of influenza While many cases of influenzal pneumonia appear to be caused by secondary pathogenic invaders there is considerable evidence that some cases of simple and apparently uncomplicated influenza may extend down into the lungs and produce a pure virus pneumonia From studies made at the Boston City Hospital it appears that the influenza virus itself may set up a considerable bronchopulmonary reaction but that in most cases in human beings secondary infection with bacteria plays an important role and may alter the pathologic picture in the lungs

In the ferret and in the mouse the influenza virus may produce pulmonary lesions almost identical with those found in fatal cases in human beings From these animals no pathogenic bacteria can be cultivated from the lungs On the other hand in swine the influenza virus gives rise to a mild upper respiratory infection and pneumonia results in this animal only when the virus is accompanied by the swine influenza bacillus

In the case of human influenza it would appear that both the virulence of the influenza virus and the prevalence type and virulence of the secondary invaders determine the severity and the character of the complicating pneumonia

For further information concerning influenza and influenza pneumonia, refer to the chapter on Influenza (p 6)

Pneumonia Caused by the Virus of Psittacosis—Psittacosis, a disease of parrots is caused by a virus which when it invades the human being leads to a severe form of atypical pneumonia A description of this type of pneumonia will be found in the chapter on Psittacosis (p 49)

Pneumonia Caused by Rickettsial Infections (Q Fever)—For some time pulmonary lesions have been recognized as part of the clinical and pathologic picture of several rickettsial diseases notably typhus and Rocky Mountain spotted fever Perhaps the most interesting and important of this group is Q fever which has been observed in both Australia and America Australian Q fever was first reported in 1937 by Derrick, who coined the name "Q fever' from Queensland where the first cases occurred

The *clinical picture* of Q fever as described by Derrick is quite characteristic with acute onset of malaise, anorexia headache muscular pains drowsiness and fever Symptoms last from seven to twenty four days with recrudescence in some cases No mention is made of pulmonary involvement in Derrick s report The infectious agent was isolated by Derrick on guinea pig inoculation and typical rickettsia were demonstrable in the spleens of infected mice Derrick named the organism *Rickettsia burnetii* after Burnet who first isolated the agent It was found that the bandicoop a native rodent of the Australian bush was susceptible to Q fever and *Rickettsia burnetii* were obtained from naturally infected ticks collected from bandicoops

American Q fever first called 'Nine Mile fever' was described in 1935 by Davis and Cox An outbreak of pneumonia ascribed to the agent of Q fever occurred among the employees of the National Institute of Health in Washington D C in the spring of 1940 An agent recovered from a number of these patients proved to be a gram negative Rickettsia like organism that grew well in tissue cultures and was identified as the Rickettsia of Q fever The *clinical features* of the pneumonia which occurred in these cases were very similar to those of the virus of atypical pneumonias which had been preva

PNEUMONIA IN CHILDHOOD

Among the serious diseases of childhood pneumonia occupies a prominent place It is one of the most prevalent of the acute diseases seen in the children's wards of hospitals and is frequently attended by grave complications and sequelae Pneumonia in the child presents a disease entity similar to pneumonia in the adult but there are differences in onset course etiology and treatment which make it advisable to give pneumonia in childhood separate consideration

As in adult pneumonia, there are two bases upon which the disease is usually classified—etiology and pathology The etiologic classification is dependent upon the infecting organism pneumococcus streptococcus staphylococcus, etc This classification is assuming more and more significance because it gives a more accurate understanding of pneumonia and also supplies a basis for specific therapy The pathologic classification divides pneumonia into lobar bronchial and certain other less common forms This classification in the last analysis is dependent upon histologic studies so that there are bound to be many clinical discrepancies Recently and particularly since the advent of the x ray the clinical differentiation of these pathologic forms has become more accurate Because there is such a marked difference in the mortality rates of the lobar and bronchial varieties of the disease this classification is also of clinical significance Pneumonia in childhood may be primary or secondary The primary pneumonia is usually of the lobar form and the secondary of the bronchial variety

Etiology —In the majority of the cases of both lobar and bronchopneumonia in childhood the infecting organism is the pneumococcus In 1979 cases of childhood pneumonia studied bacteriologically by a number of different investigators the incidence of the various organisms was found to be as follows

Organism	Number of cases	Percentage of incidence
Pneumococcus Type I	275	13 8
Pneumococcus Type II	98	5.0
Pneumococcus Type III	73	3 7
Pneumococci of other types	1272	64.3
Organisms other than the pneumococcus	263	13.3
	1979	

The striking constrast to pneumonia in the adult is the much greater percentage of pneumococcus infections of the higher type In addition there is a higher incidence of streptococcus and staphylococcus pneumonia The following table compiled by Heffron shows the incidence of the more prevalent types of pneumococcal pneumonia in childhood

Pneumococcus type	Percentage distribution in 2745 cases
XVI	12.0
I	11.2
VI	7 7
XIX	3.9
V	3 6
IV	3 1
III	2 7
VII	2.1

It is evident that the incidence of types in the pneumococcal pneumonias of childhood is quite different from that of adults

Lobar Pneumonia —Formerly it was believed that almost all of the pneumonias in childhood were of the bronchial form This impression was obtained from statistical studies on autopsies and did not allow for the low death rate in lobar pneumonia and the much higher rate for bronchopneumonia Recently by the use of more accurate diagnostic methods particularly with the assistance of the x ray it has been shown that in children as in adults lobar pneumonia has a much higher incidence than bronchopneumonia In a series of 1270 cases of pneumonia at Bellevue Hospital 1012 or 79.3 per cent were of the lobar type

The histologic characteristics of lobar pneumonia are striking Lobar pneumonia presents primarily an exudative type of inflammation in which the alveoli are filled with leukocytes red cells and fibrin causing a more or less uniform consolidation usually of lobar or confluent lobular distribution The bronchi show a simple inflammation of the mucosa but no productive changes in the bronchial walls There is usually a septal lymphangitis and a pleuritis which may be dry or form an effusion of serum or pus

Bacteriologic studies of lobar pneumonia show the pneumococcus as the exciting organism in about 90 per cent of the cases Types I VI and XIV are the strains most frequently discovered

Lobar pneumonia usually succeeds an

tive, but this does not occur with the regularity of the cough in pneumoccal or streptococcal pneumonia In many cases the dry hacking cough persists throughout the illness The sputum is mucopurulent or blood streaked never rusty The malaise and muscular aching may persist throughout the course of the disease Transient sweats occur in some cases The writer recently saw a case which was accompanied by meningismus and stiff neck but these symptoms cleared up after forty eight hours

Physical Signs —Physical examination usually reveals little in the way of positive signs As a rule the patient does not appear to be seriously ill though there are exceptions to this rule The majority of the patients show little dyspnea or cyanosis The respiration and pulse rate may be normal or only moderately increased Auscultation reveals fine or medium moist rales occurring late in inspiration Occasionally definite areas of dulness can be demonstrated by percussion

Laboratory Findings —The leukocyte count is nearly always normal The sedimentation rate may be moderately elevated The urine reveals nothing noteworthy

X-ray Findings —Several writers have noted that the x ray findings are out of proportion to the physical findings Indeed the diagnosis of virus pneumonia has been made by x ray in more than one case in which nothing more than influenza was suspected In the majority of cases x ray shows increase in both hilar shadows with areas of inflammation extending outward toward the periphery of the lung field The lower lobes are most frequently involved and in the majority of cases both lower lobes are affected The areas of infiltration are softer than those of pneumococcal pneumonia

Course —The course of virus pneumonia is usually mild though the disease may take on a severe and even fatal course The impression is quite general that virus pneumonias run a longer course than the average pneumococcal or streptococcal infection However there are many exceptions to this rule Some patients continue to run a fever for several weeks The writer recently saw a typical case of virus pneumonia in a young woman which had been going on for eight weeks, and she was still running a remittent type of fever with definite signs at both bases

Prognosis —The prognosis of virus pneumonia is usually good The patients are generally adolescents or young adults who handle the infection well Accurate statistics as to the fatality rate are not yet available, but it certainly would not be above 5 to 10 per cent

Treatment —The treatment of atypical primary pneumonia is entirely symptomatic Codeine in ½ to 1 grain (0 03 to 0 06 Gm) doses may be necessary to control the cough Expectorants are sometimes helpful If these fail steam inhalations with tincture of benzoin may give some relief Transfusions have been recommended by several writers and certainly can do no harm Sulfonamide therapy has been tried without any significant effect Indeed some think that sulfonamides increase the discomfort of the patient It would seem logical however, to try sulfonamide treatment for at least forty eight hours on the chance that one is dealing not with a virus but with an undemonstrable pneumococcal or streptococcal infection

cells which as the disease progresses produce a dense collar around the bronchi compressing and obstructing the lumina The bronchial mucosa shows a simple inflammation and the lumina become filled with a purulent secretion The air spaces around the involved bronchi are collapsed and distorted by pressure and while there is some infiltration with large mononuclear cells there is no exudate into the alveoli In bronchopneumonia the bronchi are compressed and frequently plugged with heavy purulent exudate and this in turn produces localized atelectasis and emphysema These changes are chiefly responsible for the irregular signs

Clinically bronchopneumonia is not a well defined entity The onset is indefinite and usually the extension from upper respiratory infection to bronchitis and bronchopneumonia is so gradual that it is impossible to say just when the latter does begin The temperature gradually rises but remains irregular and is usually not high The cough increases The secretions from the bronchi and upper respiratory tract become thick and purulent and are sometimes mixed with blood The respirations usually become rapid and may be painful As the toxemia increases there may be convulsions and frequently there are severe gastric and intestinal symptoms

The physical and *x ray findings* in the chest of a patient with bronchopneumonia are surprisingly few Occasionally even in an advanced case with marked toxemia physical signs are entirely normal The most constant physical finding is that of coarse rales either scattered throughout the chest or localized at the base of the lungs The x ray usually shows a generalized accentuation in the markings of the hilum and periphery In some cases generally late in the disease there are marked changes The x ray may show patchy or irregular areas of increased density representing either consolidated or collapsed lung or there may be the diffuse haziness of pleural involvement In such cases the physical examination reveals irregular areas of dulness impaired breath sounds and rales

The *diagnosis of bronchopneumonia* is made on the basis of a clinical course of severe respiratory symptoms and toxemia with the absence of localized chest signs such as are present in lobar pneumonia The temperature curve is characteristically irregular and of a spiking type The bronchial secretion differs from that in lobar pneumonia in being more profuse and of a more purulent nature The bacteriologic findings in bronchopneumonia are similar to those of lobar pneumonia but the incidence of the various organisms is different The bronchial form shows a higher frequency of streptococcus and staphylococcus infections and a correspondingly lower incidence of pneumococcus infections

The complications of bronchopneumonia are similar to those of the lobar disease The incidence of the various complications seems to depend more upon the etiologic organism than upon the pathologic form of the disease

Lipoid cell Pneumonia —In 1925 Laughlen described a type of pneumonia characterized by mononuclear cells containing fat globules so called foam cells which appear in the alveoli and alveolar walls In addition to this proliferative lesion there is a variable degree of polymorphonuclear infiltration and simple inflammation of the bronchial mucosa This condition designated as lipoid cell pneumonia is dependent upon the aspiration of oily substances The particular inflammatory reaction which follows varies with the kind of oil aspirated and with the microorganisms thus injected It is thought that the vegetable oils are the least irritating and animal fats the most so The lipoids most frequently implicated in these cases are milk fat liquid petrolatum cod liver oil and the medicated oils used in cases of infection of the upper respiratory tract

Lipoid cell pneumonia is seldom discovered previous to postmortem examination although there are a number of characteristics of the disease which should make it recognizable as a clinical entity The condition occurs in children usually in infants under two years of age who are debilitated and who give a history of having received some oily preparation over a considerable period of time The course may be acute or chronic In infants the failure to gain weight and the presence of a cough combined with rapid respirations but without dyspnea

upper respiratory infection In children the sudden rise in temperature is not as often accompanied by a chill as by vomiting or intestinal symptoms In very young children the onset is occasionally attended by convulsions With the high temperature the child is flushed and prostrated, the respirations are rapid and grunting and accompanied in most cases by a cough

As the *physical signs* in the chest are not pronounced early in the disease they are of little aid in making a diagnosis The first signs are those of slight dulness a slight diminution of the breath sounds and a few rales over the affected area The definite signs of consolidation do not appear until about the third or fourth day

The *chest roentgenogram* and *fluoroscopy* are of greater value than physical signs in diagnosing early lobar pneumonia Usually within twenty four to forty eight hours under the x ray a soft homogeneous shadow is seen over the involved lobe or area In the early stages of the disease there is an increase in the lung root markings and later a homogeneous shadow of increasing density usually extends from the root of the lung to the periphery In cases of involvement of the upper lobes the shadow is frequently triangular with the apex toward the hilum The x ray affords a clinical means of accurately differentiating between lobar pneumonia and the other pathologic varieties of pneumonia which either show no marked changes by x ray or present a picture characteristic of a different condition

The *early diagnosis* is based largely on the type of onset and the clinical course Any child showing respiratory symptoms and a high temperature should be suspected of having pneumonia An early clinical diagnosis is important in order that the infecting organism may be quickly determined and specific therapy instituted

Typing in the pneumonia of childhood is carried out in much the same way as in adults except that sputum is much less frequently obtained and hence the typing must be done on material secured either by the use of the laryngeal swab or by gastric aspiration In the swab method the posterior pharynx is irritated by the swab which initiates a cough and causes the patient to bring up a small amount of sputum or mucus This can then be used for typing by the Neufeld method Experience in a large series of cases has shown that by obtaining the material in such a way, typing can be completed almost as promptly as in the adult where sputum is available In addition to the bacteriologic studies of the bronchial secretions cultures of the blood pleural fluid spinal fluid pus from the middle ear and other localized processes should be carefully studied

The *complications* of lobar pneumonia in childhood are similar to those of the disease in adult life The most notable exception is purulent otitis media which in childhood is the most common occurring in about 15 per cent of the cases Empyema is the most frequent of the serious complications Meningitis pericarditis and endocarditis are rare complications, but when they occur they are usually fatal

The *prognosis* in lobar pneumonia is good Smith emphasizes the importance of making an accurate differentiation between lobar and bronchopneumonia because of the great difference in mortality rates of the two conditions and its consequent effect on prognosis His statistics showed a death rate of only 5.5 per cent in lobar as compared with a rate of 50 2 per cent in bronchopneumonia The mortality rate in both diseases is affected greatly by the age of the patient being very much higher in the first year of life

Bronchopneumonia —This form of pneumonia differs in many respects from the lobar type The clinical course is different It is a disease which occurs chiefly in infants and is usually secondary to bronchitis or one of the common contagious diseases of childhood It is very apt to follow an upper respiratory infection in a feeble or poorly nourished infant Clinically the incidence of bronchopneumonia is much lower than that of the lobar type In the 1276 cases of pneumonia studied at Bellevue Hospital only 264 or 20 7 per cent were bronchopneumonia

The *pathology of bronchopneumonia* is distinctly different from that of lobar pneumonia Whereas the primary feature of lobar pneumonia is an exudative inflammation which fully resolves bronchopneumonia is a productive inflammation The bronchial walls become infiltrated with mononuclear

cells which as the disease progresses, produce a dense collar around the bronchi compressing and obstructing the lumina The bronchial mucosa shows a simple inflammation and the lumina become filled with a purulent secretion The air spaces around the involved bronchi are collapsed and distorted by pressure and while there is some infiltration with large mononuclear cells there is no exudate into the alveoli In bronchopneumonia the bronchi are compressed and frequently plugged with heavy purulent exudate and this in turn produces localized atelectasis and emphysema These changes are chiefly responsible for the irregular signs

Clinically bronchopneumonia is not a well defined entity The onset is indefinite and usually the extension from upper respiratory infection to bronchitis and bronchopneumonia is so gradual that it is impossible to say just when the latter does begin The temperature gradually rises but remains irregular and is usually not high The cough increases The secretions from the bronchi and upper respiratory tract become thick and purulent and are sometimes mixed with blood The respirations usually become rapid and may be painful As the toxemia increases there may be convulsions and frequently there are severe gastric and intestinal symptoms

The physical and x ray findings in the chest of a patient with bronchopneumonia are surprisingly few Occasionally even in an advanced case with marked toxemia physical signs are entirely normal The most constant physical finding is that of coarse rales either scattered throughout the chest or localized at the base of the lungs The x ray usually shows a generalized accentuation in the markings of the hilum and periphery In some cases generally late in the disease there are marked changes The x ray may show patchy or irregular areas of increased density representing either consolidated or collapsed lung or there may be the diffuse haziness of pleural involvement In such cases the physical examination reveals irregular areas of dulness impaired breath sounds and rales

The *diagnosis of bronchopneumonia* is made on the basis of a clinical course of severe respiratory symptoms and toxemia with the absence of localized chest signs such as are present in lobar pneumonia The temperature curve is characteristically irregular and of a spiking type The bronchial secretion differs from that in lobar pneumonia in being more profuse and of a more purulent nature The bacteriologic findings in bronchopneumonia are similar to those of lobar pneumonia but the incidence of the various organisms is different The bronchial form shows a higher frequency of streptococcus and staphylococcus infections and a correspondingly lower incidence of pneumococcus infections

The complications of bronchopneumonia are similar to those of the lobar disease The incidence of the various complications seems to depend more upon the etiologic organism than upon the pathologic form of the disease

Lipoid cell Pneumonia —In 1925 Laughlen described a type of pneumonia characterized by mononuclear cells containing fat globules so called foam cells which appear in the alveoli and alveolar walls In addition to this proliferative lesion there is a variable degree of polymorphonuclear infiltration and simple inflammation of the bronchial mucosa This condition designated as lipoid cell pneumonia is dependent upon the aspiration of oily substances The particular inflammatory reaction which follows varies with the kind *of oil aspirated* and with the microorganisms thus injected It is thought that the vegetable oils are the least irritating and animal fats the most so The lipoids most frequently implicated in these cases are milk fat liquid petrolatum cod liver oil and the medicated oils used in cases of infection of the upper respiratory tract

Lipoid cell pneumonia is seldom discovered previous to postmortem examination although there are a number of characteristics of the disease which should make it recognizable as a clinical entity The condition occurs in children usually in infants under two years of age who are debilitated and who give a history of having received some oily preparation over a considerable period of time The course may be acute or chronic In infants the failure to gain weight and the presence of a cough combined with rapid respirations but without dyspnea

should suggest lipoid pneumonia The physical and x ray signs are those of a diffuse bronchial or bronchopneumonic condition The bronchial secretion is sometimes characterized by the presence of mononuclear cells containing lipoid but this has not proved to be a reliable test In all cases of suspected lipoid cell pneumonia, tuberculosis should be ruled out by application of the tuberculin test and by studies of the bronchial secretions obtained either from aspirated gastric contents or from expectorated material

The prognosis in lipoid-cell pneumonia is variable and is dependent upon a number of factors the most important being the general condition of the child, its age, the kind of oil aspirated and the degree of concomitant infection Recovery from this type of pneumonia is by slow retrogression of the process

Treatment of the active condition is for the most part symptomatic and supportive Preventive therapy is highly important In the case of debilitated infants liquid petrolatum as a cathartic or in the form of medicated nose drops should be used only with caution When cod liver oil is not easily taken one of the concentrated vitamin preparations should be substituted

Treatment —The methods of therapy used in the pneumonia of childhood are similar to those employed when the disease occurs in adults It is important however, to emphasize a few points which apply particularly to the childhood type

In prophylactic treatment, the importance of giving careful attention to bronchitis and severe upper respiratory infection in the infant is stressed It has been pointed out that in private practice where there is more opportunity for preventive measures pneumonia is quite a rare disease while in general and city hospitals it is found to have a high incidence Various hygienic measures such as good nursing quiet and comfortable surroundings, and good ventilation are of great importance and should be adopted whenever possible The food should be mostly liquid and should not be forced Water should be allowed freely at all times

Cough, pain restlessness and gastro intestinal symptoms, such as nausea vomiting distention diarrhea and constipation must each be given careful attention Along the line of symptomatic therapy *oxygen administration* has been found to be of particular value It is a means of alleviating respiratory distress and lessening to a great extent the ill-effects of anoxemia Oxygen is more easily administered to children than to adults In the case of an infant a small tent functions as effectively as an elaborate oxygen chamber *Blood transfusions* are frequently used in the treatment of the pneumonia of childhood Protracted cases and especially those in which blood studies show a secondary anemia of variable degree respond best to this therapy

Serum treatment has been displaced almost entirely by sulfonamide therapy Now serum is indicated only in the occasional patient who cannot tolerate the sulfonamides or who does not respond to them

The sulfonamide drugs one after another have been tried in childhood pneumonia as in other infectious diseases Sulfanilamide has very little value Sulfapyridine is difficult to administer because of its toxic reactions At the present time the choice is between sulfathiazole and sulfadiazine the sodium salt of either to be used when parenteral administration is required The following dosage schedule is suggested

Age	1–3 mos	6 mos–1 yr	2 yrs	5 yrs	12 yrs
Oral Dosage	0 15 Gm every 4 hours	0 25 Gm (½ tablet) every 4 hours	0.25 Gm (½ tablet) every 3 hours	0.5 Gm (1 tablet) every 4 hours	1 0 Gm (2 tablets) every 4 hours
Parenteral Dosage	0.5 Gm every 8–12 hours	1 0 Gm every 8–12 hours	1.5 Gm every 8–12 hours	2 0 Gm every 8–12 hours	2.5 Gm every 8–12 hours

All of the sulfonamides may produce serious toxic reactions and none of the drugs should be used without full knowledge of and regard for the toxic manifestations

STREPTOCOCCAL INFECTIONS

INTRODUCTION

STREPTOCOCCAL infections comprise a wide and varied group of clinical conditions It is probably not an exaggeration to state that streptococci are responsible for a greater variety of pathologic processes than any other group of bacterial agents Not only are they the direct cause of a large number of distinct diseases but owing to their wide distribution they are also important secondary invaders In addition streptococcal infections appear to initiate certain other disease processes the precise nature of which is not yet clearly understood

Classification of the Streptococci—In general streptococci are of three main varieties the *hemolytic* the *green producing* or the *viridans* and the *indifferent* The *hemolytic* streptococci constitute by far the most important of these varieties and are responsible for the great majority of streptococcal diseases The role of the *green producing* and *indifferent* varieties is largely confined to that of secondary invaders although in a certain number of conditions notably subacute bacterial endocarditis they are important primary agents

The importance of the *hemolytic* streptococci is such that they have become the subject of much intensive investigation and it is now known that there exist several distinct groups within the hemolytic variety itself The work of Lancefield which has been confirmed by numerous investigators is of particular significance in this connection Lancefield has shown by means of precipitation reactions that the *hemolytic* streptococci can be divided into distinct serologic groups, designated for convenience as Groups A B C D E F and G Of these Group A is by far the most important and accounts for an overwhelming majority of streptococcal diseases in man Thus it has been shown that practically all cases of scarlet fever acute tonsillitis erysipelas and puerperal sepsis are due to infection with Group A organisms Strains of this group may possess both toxin producing and invasive properties Strains belonging to Groups B to G are commonly found in a number of animal diseases as well as in a variety of sources in nature Such strains are also frequently found as harmless saprophytes in man but only in occasional cases are they responsible for clinical infection For example one of the natural habitats of Group D organisms is the human gastro intestinal tract but strains of this group are only occasionally pathogenic for man In a recent study Hare has further shown that only about one third of the strains of *hemolytic* streptococci found in the nose and throat of normal human beings belong to Group A The remaining two thirds of the strains belong to the essentially nonpathogenic groups B to G

The problem of classification is further complicated by the fact that there are a large number of distinct *types* within each of the various *groups* of *hemolytic* streptococci Thus Griffith has shown that there are at least 24 serologic types within Group A and probably others exist There is evidence that the distribution of these types varies in different localities and also in the same locality from time to time In general there is little indication that any particular types are more pathogenic than others but this phase of the problem requires further study While these facts reveal the complex nature of the *hemolytic* streptococci they make possible for the first time an intelligent approach to the study of the epidemiology of hemolytic streptococcal infections

Treatment—The introduction of *sulfanilamide* and its derivatives has revolutionized the treatment of hemolytic streptococcal infections Prior to what may justifiably be called the era of chemotherapy the only specific therapy available for these infections was antitoxic serum However the pathogenic action of hemolytic streptococci is in large measure due to their invasive capacity and no serum has been developed which inhibits this property Since the introduction of *sulfanilamide* and its derivatives the situation has been radically changed and there are now available highly specific chemotherapeutic agents for the treatment of hemolytic streptococcal diseases The various aspects of the treatment of individual diseases are considered in their appropriate places and it is only necessary to review certain general considerations

Sulfanilamide was originally introduced as a complex azo dye under the trade name prontosil It was soon discovered however, that prontosil owed its specific effect to a comparatively simple constituent para amino benzene sulfonamide By general agreement this substance has since become known by the term sulfanilamide A number of sulfanilamide derivatives have since been introduced which are equally effective therapeutically and exhibit less toxic properties The most satisfactory of these preparations are sulfathiazole and sulfadiazine

Sulfanilamide and its derivatives exert a remarkable chemotherapeutic effect in hemolytic streptococcal infections The precise mechanism of their action is not yet understood but it is generally agreed that they inhibit bacterial growth Sulfathiazole and sulfadiazine as well as sulfanilamide may be given by mouth and the dose recommended varies from 6 to 12 Gm (90–180 grains) daily in divided doses according to the severity of the infection Because of individual variations in absorption and excretion it is important that whenever possible the concentration of the drug in the blood should be determined frequently during the course of treatment If the drugs cannot be taken orally the sodium salts should be administered intravenously One of the untoward complications of sulfathiazole and sulfadiazine therapy is the deposition of the drugs in crystalline form in the renal tubules sometimes producing severe hematuria and occasionally renal shut down This complication can be avoided by administering bicarbonate of soda in equal amounts with the drug

ACUTE TONSILLITIS

Definition—An acute infection of the lymphatic tissue in the region of the pharynx and nasopharynx occurring in both sporadic and epidemic form The most usual variety appears as an acute inflammation of the palatine or faucial tonsils but in nearly all cases the other lymphatic tissue in this region is also involved

Anatomy—The collection of lymphadenoid tissue at the entrance to the respiratory and alimentary passages is commonly referred to as Waldeyer s or the tonsillar ring It consists of three major and several minor aggregations of lymphatic tissue The larger masses are known as the pharyngeal tonsils (the adenoids) the palatine or faucial tonsils and the lingual tonsils The smaller collections are found around the orifices of the eustachian tubes between the faucial and the lingual tonsils and in scattered patches beneath the mucous membrane of the entire nasopharynx

Histologically the tonsils are composed of lymphatic tissue similar in structure to other lymphatic glands The lymphatics of the faucial and lingual tonsils drain into the anterior group of the deep cervical glands the most important of which the tonsillar gland is found just below the angle of the jaw The lymphatic drainage from the naso pharyngeal tonsils (adenoids) is by way of the posterior cervical glands which are situated along and under cover of the posterior border of the sternomastoid muscle

Age Incidence —Acute tonsillitis is particularly prone to occur during childhood and early adult life Infants appear to possess a considerable degree of immunity and the incidence diminishes in later adult life

Seasonal Incidence —In the United States and Canada infection of the tonsils occurs most frequently during the winter and spring months reaching a peak during the month of March It is often seen among residents of hospitals at this time of year and may constitute a minor epidemiologic problem

Sporadic and Epidemic Forms —While the sporadic form of the disease is extremely common it is often possible to trace the source of the infection to another recent case Epidemics are usually confined to small institutional communities but occasionally they assume widespread proportions In the latter event the infection is of a particularly virulent nature and is more usually termed epidemic sore throat'

Etiology —Under normal conditions the tonsils harbor within their crypts a wide variety of pathogenic bacteria It is difficult to say whether the sporadic form of the disease is the result of infection by these bacteria operating under peculiarly favorable conditions or by a new pathogen introduced from without Probably infection may occur by both of these methods In the epidemic form however there can be no doubt that the agent is exogenous in nature

Although a great variety of organisms may gain access to the tonsils the clinical entity *acute tonsillitis* is for all practical purposes a hemolytic streptococcal disease There seems no basis in fact for the statement found in the older books that a variety of other organisms such as streptococcus viridans pneumococcus and staphylococcus are occasionally responsible ' Further more recent investigations have shown that in an overwhelming majority of cases hemolytic streptococci of Group A are implicated

Pathology —The tonsils are greatly increased in size and markedly hyperemic The crypts are filled with an intense inflammatory exudate of soft cheesy material which *projects from the mouths of the crypts* It is composed of disintegrating polymorphonuclear leukocytes desquamated epithelium lymphocytes and bacterial debris In more severe cases the exudate is fibrinous in character Histologically the picture is that of an acute, exudative inflammatory process in lymphatic tissue but without specific features

Symptomatology —A typical attack is characterized by an abrupt onset with severe constitutional disturbances and an acute angina of the throat There may be a definite chill or chilly sensations and the temperature rises rapidly reaching 103° to 105° F in severe cases General malaise with aches and pains in the back and extremities *are almost invariably present The tonsils* are red and swollen with patches of foul smelling exudate protruding from the orifices of the crypts In particularly severe cases the exudate may form a false membrane over the surface of the tonsils The glands in the anterior cervical region become enlarged and tender Swallowing is attended by great pain The degree of general prostration may be quite out of proportion to the severity and extent of the local lesion The acute inflammation usually subsides within four or five days leaving the patient with nothing worse than a feeling of general weakness

The foregoing account is typical of an attack of moderate severity without complications or sequelae The intensity of the disease process however varies widely and may range from a superficial inflammation with little constitutional reaction to the most profound type of septic infection with complications and sequelae much more serious than the original condition

Complications —Peritonsillitis (quinsy sore throat) and acute otitis media are the most common complications An acute suppurative cervical adenitis may follow an unusually severe attack and in the virulent, epidemic type a variety of septic complica

tions may supervene The more remote sequelae will receive brief consideration in a later section

Diagnosis —The conditions which are most commonly confused with acute tonsillitis are *diphtheria* and *Vincent's angina* (ulceromembranous tonsillitis) In *diphtheria* the appearance of the throat is usually quite distinctive The exudate takes the form of a more or less uniform dull gray membrane which leaves a bleeding surface when removed In this disease the membrane also shows a tendency to spread over the pillars of the fauces and on to the uvula In tonsillitis the exudate is distributed in yellowish gray patches separated by red and inflamed tonsillar tissue These patches can usually be wiped away leaving the underlying tissue intact In all doubtful cases cultures should be made to determine the presence or absence of *Corynebacterium diphtheriae* *Vincent's angina* is usually a unilateral infection and is associated with a superficial necrosis and a dirty yellow exudate which leaves a bleeding surface when removed In this condition constitutional symptoms are slight or absent altogether but there is usually an enlarged and tender tonsillar gland Ulceromembranous tonsillitis is commonly associated with an ulcerative stomatitis foul breath and excessive salivation The diagnosis is confirmed by the demonstration of spirilliform and fusiform organisms It is often difficult to distinguish acute tonsillitis from the pharyngeal symptoms of *scarlet fever* The local symptoms are very similar and the differential diagnosis is dependent upon the presence of systemic manifestations peculiar to the latter disease An interesting and increasingly popular conception is that many cases of acute tonsillitis occurring in individuals who possess antitoxic immunity constitute in reality *scarlet fever sine eruptione*

Treatment —In the introductory section reference was made to the use of sulfanilamide sulfathiazole and sulfadiazine in the treatment of hemolytic streptococcal infections in general These drugs exert a remarkable effect on the course of tonsillitis but their indiscriminate use in all cases is not advised In the majority of instances the infection is comparatively mild and terminates spontaneously in a few days In the more severe type of case however the administration of one of these drugs is definitely indicated The dose recommended is from 6 to 8 Gm (90–120 grains) daily in four divided doses Untoward symptoms accompanying the use of sulfanilamide include nausea and vomiting dizziness and more rarely, cyanosis and pyrexia Sulfathiazole and sulfadiazine produce significantly fewer toxic reactions With these drugs it is wise to administer an equal quantity of bicarbonate of soda to prevent possible renal damage The following general measures are indicated in the treatment of acute tonsillitis The patient should be kept in bed and given large quantities of fluids until the acute attack is over The gastro intestinal tract should be properly regulated An ice bag should be provided for the neck and the mouth kept clean by the frequent use of a mouth wash The most effective local treatment consists in the application of hot irrigations directly to the surface of the inflamed tissues Either physiologic saline or a 2 per cent solution (1 teaspoonful to 1 quart) of sodium bicarbonate may be employed Symptomatic relief may be obtained by the use of acetylsalicylic acid (aspirin), Dover's powders or codeine

M H Dawson

SEPTIC SORE THROAT

(Septic Pharyngitis Epidemic Sore Throat)

Septic sore throat is a severe infectious disease which involves the tissues of the pharynx generally and which frequently occurs in epidemic form It will be recalled from the description of the anatomy of the tonsillar ring that the lymphatic tissue is widely distributed throughout the pharynx and the nasopharynx This is the tissue through which the infection enters and the resulting inflammation more or less diffusely involves the entire pharynx From the bacteriologic and pathologic points of view there is little justification for the separation of septic sore throat from acute tonsillitis For the clinician however the distinction serves a certain useful purpose and the term is usually employed to describe an acute tonsillitis of unusual severity which may have assumed epidemic proportions

Incidence —The disease occurs in both sporadic and epidemic forms The most striking examples of the latter variety have been due to milk borne infections in which the milk supply has been contaminated from human sources

Etiology —The hemolytic streptococcus is exclusively responsible for the production of this clinical syndrome It was formerly believed that a specific type of encapsulated organism the *Streptococcus epidemicus* was involved but more recent studies suggest that this organism is merely the mucoid variant of ordinary Group A hemolytic streptococci

Pathology.—The lesions first appear in the lymphoid tissue of the tonsillar ring and spread to involve the mucous membrane of the entire pharynx No distinctive features other than those of an acute fibrinopurulent exudate are present.

Symptomatology —The symptoms are essentially identical with those of the more acute form of follicular tonsillitis and it is often difficult or even impossible to distinguish between the two conditions

Complications —The complications of this condition are similar to those which occur in acute tonsillitis but they are apt to be more serious and of more frequent occurrence The infection may gain access to the blood stream or may spread downward to involve the tissues of the larynx and epiglottis In other cases deep cervical adenitis with suppuration may occur In a certain number of instances the infection travels via the lymphatic channels to the mediastinum and thence to the lining membranes of the heart and lungs

Diagnosis —The disease must be distinguished from diphtheria with which it is even more likely to be confused than is the ordinary acute tonsillitis In all suspicious cases the diagnosis should be confirmed by smear and culture

Treatment.—The treatment is the same as that of acute tonsillitis The administration of sulfanilamide sulfathiazole or sulfadiazine is indicated to prevent the development of complications or sepsis Since the introduction of chemotherapy the use of antistreptococcal serum has been abandoned

M H Dawson

PERITONSILLITIS

(*Peritonsillar Abscess, Quinsy Sore Throat*)

Peritonsillitis more commonly known as quinsy is an acute suppurative inflammation of the loose connective tissue between the capsule of the tonsil and its muscular bed Because of the anatomic relationships the collection of pus is usually confined to the upper two thirds of the tonsillar bed and the adjacent region of the palate In consequence the upper pole of the tonsil is pushed downward and medially the lower pole being more or less fixed in position by its attachment to the lateral wall In spite of the position and extent of a peritonsillar abscess the pus rarely extends down into the deeper tissues of the neck

Incidence —The disease shows a special predilection for young adults being relatively rare in children and in later adult life As is the case with other hemolytic streptococcal infections peritonsillar abscesses are more frequent in the late winter and early spring months

Etiology —Peritonsillar abscess may occur as a complication of simple tonsillitis but more frequently develops in those whose tonsils have been the site of repeated suppuration and cryptic retention The appearance of a tonsil in which an abscess is likely to develop is in no way distinctive The submerged type in which the openings of the crypts are hidden and obstructed is however frequently affected One attack confers no immunity but rather increases the susceptibility to subsequent attacks of the same nature *Streptococcus haemolyticus* is almost invariably the specific inciting agent

Symptomatology —The symptoms of peritonsillitis are similar to those of acute tonsillitis although as a rule the constitutional disturbances are less marked and there is not as much fever On the affected side the patient experiences great pain which often radiates to the ear Deglutition becomes painful and difficult the head is held rigidly and is often bent forward to the affected side The muscles of mastication are set to avoid movements of the jaw and there is copious secretion of tenacious saliva

The appearance of the throat is very characteristic On the involved side there is marked redness swelling and edema of the

palate and uvula and the tonsil is pushed downward and forward In a limited number of cases the process may be bilateral As the abscess increases in size the palate becomes more swollen and the uvula is pushed toward the opposite side In the majority of cases the center of the abscess occupies a position midway between the base of the uvula and the last upper molar tooth but occasionally the abscess points in other directions The duration of an untreated abscess varies considerably but it will usually rupture spontaneously in about a week's time

Complications —Complications of peritonsillar abscess are fortunately rare Edema of the glottis may occur In occasional cases the process may extend down into the deep cervical tissues producing thromboses and septic emboli

Treatment —The treatment consists in relieving the acute symptoms and evacuating the pus at the earliest possible moment Surgical interference is usually possible within thirty six or forty-eight hours and it is not necessary to wait for the development of fluctuation Sulfanilamide sulfathiazole and sulfadiazine may be ineffective in this condition because of the inhibitory action of large purulent exudates However these drugs may be administered in the hope that recovery will be hastened and complications prevented In the meantime the patient should be made as comfortable as possible It is often wise to administer morphine An ice bag should be provided for the neck and hot irrigations applied directly to the inflamed area at frequent intervals If possible fluids should be forced If they cannot be taken orally they should be given parenterally After evacuation of the pus hot saline irrigations should be continued to hasten resolution of the process Convalescence should not be hurried and every means should be taken to restore the patient's general health Particular attention should be paid to the urine in the following weeks for glomerular nephritis is a not infrequent sequela In order to prevent the occurrence of future attacks tonsillectomy is indicated This should not be done until a month or more after the subsidence of all acute symptoms Tonsillectomy when carefully and thoroughly performed almost invariably prevents subsequent attacks even in the most susceptible individuals

M H Dawson

ADENOIDS

Simple hypertrophy of the lymphatic structure of the pharynx is a more or less physiologic process during childhood but it frequently assumes pathologic proportions especially in the region of the pharyngeal tonsils and leads to the development of a characteristic clinical syndrome—adenoids

Pathology —Although the pharyngeal tonsils are subject to the same inflammatory processes which affect the palatine tonsils the most common pathologic change is one of simple hypertrophy The harmful effects of adenoids are in large measure due to the mechanical obstruction which they produce in the air passage and at the orifices of the eustachian tubes

Etiology —The exact cause of hypertrophy of the pharyngeal tonsils is not known The condition occurs most frequently between the fifth and tenth years and shows a tendency to involve more than one member of the same family It is said that the acute infections of childhood are apt to be followed by hypertrophy of this tissue but it is often difficult to determine which is cause and which is effect The same may be said of the relationship between repeated attacks of the common cold and adenoids Possibly a vicious circle is set up in which each condition in turn leads to the development of the other

Symptomatology —Adenoids produce a varied group of clinical symptoms of which mouth breathing is the most frequent and the most characteristic This is particularly noticeable at night and may be the cause of *snoring restless nights* and a feeling of suffocation The voice is thick and of a distinctive nasal quality difficulty is experienced in pronouncing certain consonants requiring nasal resonance Children with adenoids are especially prone to suffer from repeated attacks of upper respiratory infection—common colds sinusitis and recurring sore throats Owing to interference with drainage from the eustachian tubes acute and chronic infections of the middle ear are common

complications The only symptom may be slight deafness but examination frequently will reveal the presence of thickened and retracted membranes

The foregoing symptoms are those commonly associated with mild degrees of hypertrophy of the pharyngeal tonsils In more severe cases profound constitutional disturbances may result There may be definite retardation in both physical and mental development The face becomes lengthened the alae nasi collapsed and the upper lip shortened and retracted these changes together with the open mouth give the countenance an expression of stupidity so characteristic that it has been termed the *adenoid facies* Fortunately owing to the general education of the public improvement in hygienic conditions and routine examination of children of school age examples of this condition are becoming increasingly rare

Diagnosis —In well marked cases the diagnosis presents no difficulty In mild cases a history of recurring attacks of rhinitis with associated episodes of deafness with or without pain in the ears is most suggestive A most valuable sign in doubtful cases is the size of the lymphatic glands in the *posterior* cervical triangle just behind the border of the sternomastoid

Treatment —The only treatment consists in immediate and thorough removal by surgical methods The procedure is a very simple one and should be routinely performed when tonsillectomies are done for any reason The prognosis depends entirely upon the length of time for which the symptoms have persisted prior to operation

M H Dawson

CHRONIC TONSILLITIS

The term *chronic tonsillitis* as ordinarily employed is restricted to diseases of the palatine tonsils However it is only necessary to recall the anatomic distribution of the lymphatic tissue in the pharynx and nasopharynx in order to realize that inflammatory conditions are rarely confined to one portion of the tonsillar ring alone This is a most important point not only in relation to diseases of the tonsils themselves but also in regard to systemic diseases in which the tonsils may be considered to act as foci of infection Chronic tonsillitis includes conditions of both a hypertrophic and a chronic inflammatory nature

Chronic (Hypertrophic) Tonsillitis— At the outset it must be emphatically stated that enlarged tonsils are not necessarily diseased tonsils Some degree of hypertrophy of the lymphatic tissues of the pharynx is a physiologic process in children up to the age of puberty Such simple enlargement is not injurious to the individual unless it causes mechanical obstruction or unless it renders the patients susceptible to repeated attacks of sore throat However it is an exceedingly difficult problem to distinguish between physiologic and pathologic hypertrophy Excessive hypertrophy is of course readily recognized but there is a great middle ground where opinions vary widely In this connection it must also be kept in mind that hypertrophy of the tonsils is by no means synonymous with prominence of the tonsils Tonsils which are apparently small and buried may be actually quite as large as those which protrude more obviously into the oral cavity

Simple hypertrophied tonsils are enlarged pale in color and firm in consistency The symptoms for which they are responsible are essentially the same as those which have been described in the foregoing section on adenoids Treatment consists in surgical removal other procedures are not recommended

Chronic (Inflammatory) Tonsillitis— Chronic inflammatory tonsillitis is even more difficult to define than hypertrophy of the tonsils Some degree of inflammation is present within all tonsils and a distinction between that which is physiologic and that which is pathologic is almost impossible Practically all tonsils contain within their crypts considerable quantities of inflammatory exudate as well as a variety of pathogenic organisms The physician should therefore exercise great restraint before frightening his patients with unwarranted statements as to the condition of the tonsils

The term chronic inflammatory tonsillitis can justifiably be employed to describe that condition in which after an acute attack the tonsils remain enlarged

congested and edematous Such tonsils are highly susceptible to the development of subsequent attacks and are frequently the site of small abscesses Peritonsillar suppuration is a common complication After several attacks it is not unusual for the tonsils to shrink and atrophy leading to the development of the so called 'buried tonsil' In these cases the tonsils may be hard and fibrous but they frequently contain small suppurative foci

The foregoing type of chronic tonsillar infection will cause little confusion but there is a variety of other conditions in which the situation is much less clear The problem of chronic tonsillar infection as it affects the general health of the individual is an especially difficult one So too the relation between foci of infection in the tonsils and many systemic diseases is most perplexing In the majority of cases these relationships remain obscure even after the most careful and painstaking examination of the tonsils themselves The most innocent-looking tonsils particularly those of the small and buried type may harbor more infection than those which are large and prominent Furthermore definite infection of the tonsillar tissue may be present without leading to the development of any symptoms One of the most reliable signs of chronic tonsillar infection is the size and condition of the glands at the angle of the jaw Chronic enlargement of these glands with or without tenderness is probably a more valuable sign of chronic inflammation than either the history or the size and appearance of the tonsils themselves

M H DAWSON

TONSILLITIS IN RELATION TO SYSTEMIC DISEASES

Systemic diseases arising as a result of tonsillar infection are of 2 main varieties (1) those of a septic nature in which organisms, usually hemolytic streptococci gain access to the body through acutely inflamed tonsils and (2) those of a less clearly understood nature in which bacteria cannot be demonstrated in the more remote organs and tissues but which appear to be in some way related to infection of the tonsils themselves The former group the acute septic conditions are comparatively rare but examples of suppurative pericarditis pleurisy peritonitis arthritis and septicemia are occasionally seen Such events occur most frequently in the course of severe epidemics The latter group comprises a number of serious diseases among which may be mentioned rheumatic fever, rheumatoid arthritis glomerular nephritis various forms of non articular rheumatism infectious jaundice certain of the erythemas some cases of asthma and a variety of other conditions The mechanism involved in the pathogenesis of this group of diseases remains imperfectly understood Theories based on allergy or hypersensitiveness have many proponents Other investigators feel that, although certain of the manifestations of these diseases may be allergic in nature such an explanation is inadequate to account for the disease pictures in their entirety At the present time it is necessary to reserve judgment concerning the precise etiology of this entire group of diseases From the practical point of view the question of tonsillar infection in relation to systemic disease more or less resolves itself into a consideration of the indications for tonsillectomy

Indications for Tonsillectomy—While no hard and fast rules can be laid down which will serve as a guide in each individual case certain general principles can be stated The indications for tonsillectomy may be divided into two categories (1) local conditions in the throat (2) systemic diseases

(1) *Local Conditions*—Recurring attacks of acute tonsillitis peritonsillar abscess hypertrophy of the tonsils sufficient in degree to cause obstruction to breathing or to produce aural complications chronic cervical adenitis when other causes have been excluded

(2) *Systemic Diseases*—Tonsillectomy should be carefully considered in rheumatic fever glomerulonephritis early cases of rheumatoid arthritis and in the following conditions especially if there has been a history of preceding attacks of sore throat various forms of nonarticular rheumatism recurring attacks of bronchitis certain erythemas and symptomatic purpuras certain cases of bacterial asthma iritis which has proved refractory to other forms of treat

ment and a variety of other conditions In addition the procedure is sometimes indicated in patients who are underweight and in general poor health for no apparent reason In spite of this wide range of indications a conservative attitude should be adopted For example there is little evidence that tonsillectomy favorably affects the course of rheumatic fever and the procedure should be recommended more as a general health measure It should never be carried out during the active stages of this disease In rheumatoid arthritis tonsillectomy appears to be of some value in the early stages of the disease but in more chronic cases the results are usually disappointing In general it is the author s opinion that the question of focal infection has been greatly overemphasized in contemporary American medicine and that the time has come when the entire problem should be very critically reviewed

M H Dawson

ERYSIPELAS

Definition —Erysipelas is an acute inflammatory disease of the skin or more rarely, of the mucous membranes caused by the *Streptococcus haemolyticus* The dermal manifestation is accompanied by fever and constitutional symptoms

History.—The disease has been recognized since ancient times and its contagious nature has been known since the middle of the nineteenth century Fehleisen in 1882 demonstrated the streptococcus in the skin and reproduced the disease in animals and man by the inoculation of pure cultures In the preaseptic era erysipelas was a common and virulent infection frequently assuming epidemic proportions The introduction of a epsis did much to rid the disease of its terrors and in modern times epidemics have only occurred as the result of unhygienic conditions or the neglect of preventive measures

Another milestone in the history of erysipelas occurred with the introduction of modern chemotherapy the disease responds in dramatic fashion to the sulfonamide compounds and is now rarely a serious problem

Incidence —At present the disease is endemic in most communities its distribution corresponding with that of other hemolytic streptococcal infections It is more frequently encountered in temperate climates and in the spring of the year Individuals of all ages are susceptible the greatest incidence occurring between the ages of thirty five and fifty five years

Etiology —The exciting organism is *Streptococcus haemolyticus* The evidence strongly suggests that only organisms belonging to Group A (Lancefield) are implicated but strains belonging to any one of the twenty six or more types (Griffith) of Group A may act as initiating agents The concept of a specific erysipelas strain has been abandoned In occasional instances staphylococcus may give rise to a similar clinical picture

Infection always takes place at the site of a wound fissure or abrasion which is often too small to be visible to the naked eye It may be due to the introduction of organisms from external sources or to self infection as in chronic rhinitis and operations on infected areas A predisposing cause is lowering of resistance for any reason Patients who have recently undergone a surgical operation and women after parturition are particularly susceptible as well as patients with chronic alcoholism or debilitating disease

Morbid Anatomy —Microscopically the condition is one of edematous dermatitis with little fibrinous exudate and only moderate infiltration with leukocytes Suppuration takes place if the disease extends to the subcutaneous tissues Organisms are found only toward the margin of the lesion where they may occur in great numbers in the lymphatic spaces General sepsis is now rarely encountered

Symptoms —After a short incubation period of one to three days the disease sets in abruptly often with a chill accompanied by fever vomiting and symptoms of general toxemia—malaise headache and anorexia The dermal manifestation is usually noted simultaneously with or shortly before the appearance of general symptoms In 90 per cent of cases the local lesion is situated on the face usually beginning at the nostril or bridge of the nose occasionally on the lip or ear Other points of origin are the lower extremities usually from an abrasion or sore surgical wounds the umbilicus in the newborn and the vulva during the puerperium

Wherever it may start the local appearances are much the same A small area of

the skin becomes red and swollen and is tender on pressure The process spreads rapidly, the margins being sharply marked, elevated and indurated on *palpation*, constituting the characteristic "wall" In areas where the skin is very loose no 'wall' is formed Small vesicles or larger blebs frequently develop Small, red tonque shaped projections may be seen at the periphery, marking the advance of the disease in the *lymphatics Extension is always by* continuity, when this is apparently not the case careful inspection shows that the two inflamed areas are joined by reddened lymphatics Rarely two or more widely separated rashes are seen the result of multiple inoculation Involution takes place after a *few days in the parts first involved while* the process is still spreading at the periphery, the skin becomes paler and less swollen the blebs dry up into crusts, and finally there is a profuse flaky desquamation The regional lymph nodes are enlarged, but are difficult to palpate on account of the swelling of the overlying skin

In *facial erysipelas* the lesion spreads rapidly on the cheek and over the bridge of the nose to the opposite side giving the familiar 'butterfly' appearance The features are greatly distorted, the eyelids so swollen that the eyes cannot be opened the conjunctivae intensely reddened the skin of the face and ears swollen red tense and shiny and covered with vesicles or blebs On the forehead the process usually stops at the hair line in about 12 per cent of facial cases however it involves the scalp and does not stop until the nape of the neck is reached These natural stopping places of erysipelas are at the barriers where the skin is tightly bound down to the underlying structures For this reason erysipelas rarely passes down over the chin on to the front of the neck Occasionally it does not stop at the nape of the neck but extends to the back *it is then likely to spread over* wide areas and even over the entire body

In untreated cases the disease usually lasts from four to eight days Recrudescences and relapses are not uncommon and are ushered in by an increase or return of the fever In such cases there may be a recur*rence of* the inflammation at the site of last involvement rarely the parts first affected may be involved a second time Termination by crisis is common in untreated cases

The blood shows an increase in polymorphonuclear leukocytes Blood cultures are negative unless there is a complicating septicemia Erysipelas is a disease with a marked tendency to recur, as many as 20 per cent of patients have two or more attacks Occasionally, repeated attacks may occur and *in such* instances the skin may become greatly thickened as in elephantiasis and may remain in this condition permanently

Erysipelas of the mucous membranes is much less common It occurs chiefly in the pharynx and fauces, sometimes in the nose and is characterized by an intense diffuse redness and swelling with much pain Very rarely it occurs in the larynx and may lead to stenosis and death by suffocation The lesion may spread to the skin of the face but extension in the opposite direction *ie* from the skin to the mucous membranes is rare Occasionally the vulva is the primary site of erysipelas during the puerperium and extension often takes place to the adjacent skin more rarely to the endometrium

Complications —Abscess formation is by far the most common and important of the complications occurring in 10 per cent of untreated cases Sometimes the inflammation *leads to superficial gangrene or slough*ing especially over the ears the tip of the nose the ends of the fingers and toes Suppuration may take place in the frontal sinus or antrum further extension may occur and lead to thrombosis of the cavernous sinus meningitis or cerebral abscess Further com*plications may be expressions of a* septicemic process which is prone to occur in debilitated subjects

Preexisting chronic disease is sometimes favorably influenced by erysipelas *Occa*sionally malignant tumors undergo a pronounced recession or lupus of the skin or varicose ulcers may heal after an attack in leukemia the white count may drop temporarily to normal

Diagnosis —The characteristic appear*ance of the local eruption* especially of the sharply defined raised advancing margin the presence of vesicles on the surface and the inflammation of the neighboring lymph glands are usually quite *distinctive The*

combination of this lesion with the sudden onset of constitutional symptoms and high fever produce an unmistakable picture Occasionally a diffuse cellulitis or inflammatory edema extending from a carbuncle or furuncle may present a somewhat similar local appearance but the characteristic wall like margin is absent and constitutional symptoms are minimal Acute eczema and dermatitis may lead to confusion but in these conditions the skin is more indurated and less tender and constitutional symptoms are lacking

Prognosis —Erysipelas in the sporadic form as seen at the present time is an almost benign disease This is especially true since the introduction of the sulfonamide drugs Even in untreated cases the ordinary attack of erysipelas usually leads to complete recovery leaving no residue or defect. Formerly the mortality varied from 5 to 10 per cent, the great majority of fatal cases occurring in elderly debilitated or cachectic patients and in newborn infants

Prophylaxis —The patient should be isolated during the attack and the ordinary precautions of disinfection should be taken Cases of erysipelas should never be treated in the vicinity of surgical or maternity cases or by those in attendance on such cases

Treatment —The introduction of the sulfonamide compounds has rendered all other forms of treatment obsolete Sulfanilamide sulfathiazole and sulfadiazine are all effective but sulfadiazine produces fewer toxic reactions When these drugs are administered a prompt drop in temperature results the spread of inflammation is checked and complications seldom occur A dose of 6 Gm (90 grains) during the first twenty four hours followed by 3 to 4 Gm *daily for three to four days* is usually sufficient to check the disease The administration of an equal amount of sodium bicarbonate will prevent the development of renal toxicity due to the drug After the institution of treatment the temperature returns to normal within twenty four hours in approximately half of the cases and in only rare instances does fever persist for seventy two hours

Local applications are not needed apart from a simple greasing of the skin The use of serum therapy antitoxins and vaccines together with radiotherapy and ultraviolet light have been completely abandoned

The patient should be kept in bed on a bland diet until the temperature has been normal for two to three days Symptomatic medication may be needed, aspirin for headache and barbiturates for insomnia are usually sufficient

The tendency to *recurrent attacks* is best met by treatment of the chronic infection which is usually the cause (sinusitis eczema ringworm of the feet) The use of vaccines and streptococcal filtrates is recommended by some as a prophylactic measure

SCARLET FEVER

Definition —Scarlet fever is an acute infectious disease caused by the *Streptococcus scarlatinae* and characterized by a sore throat and a punctate rash on the skin and roof of the mouth followed by desquamation

History.—Scarlet fever in early times was confounded with measles and rubella It was first definitely described by Sydenham in 1675 under the name of "febris scarlatinae" as a mild, harmless disease It was undoubtedly observed by Ballonius in a Paris epidemic of 1574 and in 1619 Sennert in Germany accurately described the disease The severe epidemics of diphtheria in the eighteenth century led to much confusion with scarlet fever and this in a measure was not cleared up until the discovery of the diphtheria bacillus

Incidence —*Age* —Scarlet fever is essentially a disease of early childhood The susceptibility is particularly great from the time of appearance of a positive Dick test to the eighth year According to McCollum the mortality is 33 per cent in the first year

about 25 per cent in the second and third years, and then gradually drops to 3 to 5 per cent in the eighth year where it remains throughout life The disease is practically unknown in the tropics

Race—The black race is relatively immune to the disease as compared with the white The yellow races also show an increased immunity as demonstrated by the Dick test

Seasonal Incidence—Epidemics are more common in the fall and winter, and gradually subside in the summer The relation between school attendance and the numerical distribution of scarlet fever cases during the year is very evident

Immunity—The newborn infant usually gives a negative reaction to the Dick test even when its mother gives a positive reaction for the infant has never become sensitized to the scarlatinal streptococcus This reaction to the Dick test corresponds to the negative tuberculin reaction of the nontuberculous infant The susceptibility in families seems to vary essentially with age Sometimes in large families when no quarantine is possible only a single member contracts the disease There is a definite tendency however for some families to react violently to scarlet fever three or more children dying in a relatively mild epidemic Certain families seem to be predisposed to the complicating nephritis Infants with exudative diathesis are particularly subject to a severe form of scarlet fever especially the anginose type

Other Diseases as Predisposing Factors—*Infections of the throat* seem to predispose to scarlet fever Schick cites three instances of scarlet fever *infection after* an attack of diphtheria in physicians who had previously worked in scarlet fever wards without contracting the disease Further predisposition to the disease seems to be caused by *surgical wounds puerperium* and *injuries* particularly burns

The Portal of Entry—That the pharynx is usually the portal of entry is evidenced by the primary localization there In exceptional cases the streptococcus of scarlet fever may enter through an operative wound a burn, the uterus at childbirth or an injury received during the postmortem examination of a scarlet fever patient

Etiology—The studies of Dick and Dick and of Dochez definitely established the etiologic relationship of the *Streptococcus haemolyticus* to the disease The evidence for this may be stated briefly *Streptococcus haemolyticus* is regularly found in the initial local lesion of the disease scarlet fever has been transmitted experimentally to man by inoculation with a pure culture of scarlatinal streptococci, the sterile filtrate from a broth culture of *S scarlatinae* causes a local reaction in the skin of persons susceptible to scarlet fever, but no reaction in those who are immune Toyoda and Fugati have shown that Dick s toxin contains both a heat labile and a heat stable toxin The latter toxin produces in certain individuals an allergic reaction that is probably responsible for the positive Dick tests in immune individuals If given subcutaneously to a susceptible person the sterile filtrate causes a general reaction with a typical scarlatinal exanthem immunization with the filtrate induces an active immunity to scarlet fever serum from *horses immunized with scarlatinal streptococci* specifically blanches the rash in scarlet fever neutralizes the toxin in the blood of patients and cures the toxic phase of the disease, convalescent scarlet fever serum *neutralizes the toxic action of culture filtrates*

Mode of Infection—In most cases infection occurs by direct contact The scarlet fever streptococcus can persist for weeks in garments, books toys and other articles and is thus more easily transmitted by a third party than are some of the other infectious diseases It can be conveyed by milk from cows infected with mastitis caused by *Streptococcus scarlatinae* or infected during its handling by an individual harboring the specific streptococcus Recent observations have shown that infection of the throat and pyogenic infections with *S scarlatinae* the so called *scarlatina sine exanthemata* are more frequent than had hitherto been supposed and that they may be an important factor in the spread of scarlet fever

The *incubation period* is variously estimated to last from one to eleven days it is occasionally longer the usual length of time being from two to five days

It is probable that scarlet fever is not communicable during the period of incuba

tion and that it is only slightly so at the onset of the disease The presence of discharges from the nose and throat should determine the length of quarantine In mild cases when discharges from the upper respiratory tract are absent an interval of three to four weeks seems to be sufficient to prevent the spread of the infection

Morbid Anatomy —The morbid anatomy of scarlet fever is not characteristic The typical renal lesions are characterized particularly by infiltration of the cortex with plasma cells around the glomeruli and the blood vessels Diffuse glomerular nephritis is characteristically associated with scarlet fever during the second and third weeks of the disease

Symptoms —The onset of scarlet fever is usually very abrupt Vomiting is one of the most constant early symptoms When seen soon after onset the patient has a high fever the skin is dry and there is a tendency for the cheeks to be reddened while a peculiar pallor is noticeable around the mouth and nose (circumoral pallor) The temperature generally rises very rapidly to between 103° and 105° F Although the face is flushed there is no definite *rash* until six to twenty four hours later when numerous fine red macules appear around the hair follicles and by confluence produce a deep blush of the skin The rash usually appears first on the neck behind the ears and on the chest gradually spreading within twenty four hours to the arms and legs In more severe cases it assumes a more definitely papular form resembling goose flesh because of the *localization around the hair follicles* When the scarlet fever is still more severe little vesicles may form on the papules In the mild cases and sometimes in a severe case it may be patchy and restricted to the soft folds of the axilla the elbow the groin and inner aspect of the thigh On the lower extremities small areas of a punctate rash around the hair follicles on the dorsum of the foot are often the only local evidence of a rash In *malignant scarlet fever* the rash often becomes hemorrhagic It can be entirely obliterated by pressure in the early stage the anemic area persists for a certain length of time the rash returning in pin points around the hair follicles on a definitely yellowish background (icteric) The skin usually feels hot and dry, and is slightly edematous Itching is a variable symptom not dependent on the severity of the rash Since in mild cases the rash may appear in small areas and persist for only a few hours it is of the utmost importance to examine the entire body repeatedly for its presence

Quite as characteristic as the rash is the *enanthem* on the soft palate and roof of the mouth which consists of a fine punctate eruption and is perhaps, the most constant sign of scarlet fever In the early stage the tongue is heavily furred tending to be red at the tip and sides the papillae are definitely enlarged and occasionally show through the thick fur in the center In the course of a few days the heavy white membrane desquamates leaving the tongue smooth and red with numerous large papillae on its surface—the so-called *raspberry* or *strawberry tongue*

The *pharyngeal symptoms* are definite although there may be only slight redness or injection of the fauces particularly in patients without tonsils If the tonsils are present there is generally definite swelling and in most instances a follicular exudate When the disease is severe the patches of membrane may coalesce so as to resemble that of diphtheria If in the first two days of the disease the membrane spreads beyond the tonsils it is often due to complicating diphtheria The swelling involves all of the pharyngeal structures

Secondary to the throat infection there is *swelling of the glands of the neck* particularly the so called tonsillar gland at the *angle of the jaw There is a general adenopathy* and in most cases the axillary inguinal and cubital glands are palpable

The *temperature* usually reaches its maximum within twenty four hours continues high for from three to five days and then gradually falls by lysis The height of the fever indicates the severity of the infection

The *pulse rate* usually ranges from 120 to 160 In the septic cases with marked cyanosis the pulse is very weak and can be felt only with difficulty

There is generally a very definite *polymorphonuclear leukocytosis* the white cell count varying from 15 000 to 30 000 or more The polymorphonuclear cells constitute from 85 to 95 per cent of the leukocytes Of particu

lar value is the relative increase of eosinophils to 5 per cent and above after an initial drop Mild cases of scarlet fever can often be distinguished from tonsillitis by the persisting eosinophilia A low leukocyte count and low eosinophils denote a bad prognosis

At the onset of the disease there is usually *mild albuminuria* with no further evidence of renal irritation The *involvement of the nervous system* is generally in proportion to the height of the fever *Diarrhea* occurring late in the septic type may be caused by streptococcic enteritis

Desquamation is one of the most typical signs of scarlet fever As a rule the degree is directly proportional to the severity of the rash The process begins on the chest and progresses as did the rash It is usually complete in from two to three weeks on the body and may continue for from four to seven weeks on the palms of the hands and soles of the feet When the disease is mild desquamation is later than when it is severe but usually there is an interval of from three to ten days between the disappearance of the rash and the first indication of desquamation During this period diagnosis of scarlet fever is sometimes very difficult and the only indication of the disease may be the breaks in the skin below the nails of the fingers and toes which can be seen when the ball of the finger or toe is pulled away from the nail In infants desquamation is usually insignificant Complete casts of hands and feet have formed in severe cases The secondary desquamation due to rapid drying of newly formed skin makes it difficult to determine the end of primary desquamation

Varieties of Scarlet Fever—Scarlet fever may be present without eruption fever angina or desquamation Mild scarlet fever is usually very difficult to recognize unless there is an epidemic There is generally a mild sore throat and a rash which develops only in patches in the folds and persists for from twelve to twenty four hours In mild epidemics a sore throat is often the only manifestation of the disease Sometimes there may be subsequent desquamation even if careful observation has revealed no rash Isolation of the specific streptococcus of scarlet fever helps to differentiate these cases An individual who gives a negative reaction to the Dick test may have tonsillitis caused by the *Streptococcus scarlatinae* This probably accounts for the frequency with which children come down with scarlet fever following tonsillitis in one of the parents

The *usual form* of scarlet fever is characterized by a sudden onset, with vomiting and a rise of temperature to 103° F within a few hours, followed by the appearance of a rash on the neck and chest which covers the entire trunk and extremities during the next two days, and persists for from four to five days before its gradual subsidence The desquamation as a rule begins eight or ten days after onset The throat usually shows the typical follicular tonsillitis, with considerable swelling of the fauces, and the typical punctate rash appears on the soft palate and roof of the mouth The characteristic strawberry tongue and moderate adenopathy are present The patient is usually very uncomfortable because of the high fever general malaise and painful sore throat Five or six days later, when the fever and sore throat have disappeared the patient feels ready to get up a fact which makes the subsequent isolation of about four weeks irksome and frequently very difficult to manage

Severe scarlet fever can be divided into the *fulminating toxic type* and the *anginose* or *septic type* In the first the patient is overwhelmed by the infection and dies within twenty four to forty eight hours from rapid heart failure without manifesting any very definite signs indicative of the disease The rash may be merely a blush with a patchy appearance over the trunk and extremities and none of the characteristic punctate features There is usually marked cyanosis and the patient is stuporous generally in a state of constant increasing delirium Another toxic type is manifested by high fever great restlessness headache delirium and an intense scarlet rash which is often hemorrhagic There may be hyperpyrexia the temperature rising to 108° or 110° F Death as a rule takes place within from forty eight to seventy two hours The two toxic types are due to the specific scarlet fever toxin and if treated early respond to the antitoxin

In the *anginose* or *septic form* of scarlet

fever the severity of the throat infection is the most striking feature The exudate from the tonsil becomes confluent and spreads to the other structures of the throat There is dysphagia and difficulty of respiration discharge of a profuse serosanguineous material from the nose and often early involvement of the paranasal sinuses and middle ear This condition resembles that of malignant diphtheria and the process may involve the larynx and trachea If death does not occur in this acutely septic state there may be marked sloughing of the throat with formation of deep abscesses and general sepsis Often a cuirass like swelling develops This type is seen more often in infants and young children

Sequelae —The sequelae of scarlet fever are so common that they have come to be regarded as merely a second phase of the disease (Pospischill s *Scharlach zweite Erkrankung*) which usually develops after an interval of from ten to fourteen days It is in this second period that the so called sequelae —otitis media sinusitis adenitis nephritis arthritis and gangrene—occur At the end of the first week the patient with the usual type of scarlet fever has a normal temperature and is free from symptoms but not until the fifth week has passed is he safe from the second phase

Angina Tonsillitis Cervical Adenitis and Cellulitis —As in the primary infection there may be very definite angina and tonsillitis associated with severe pain dysphagia and difficulty in speaking Peritonsillar and retro pharyngeal abscesses are not uncommon The infection particularly in young children may spread beyond the glands so that the entire neck is indurated The skin becomes tense and drawn the head is retracted and there may be considerable dyspnea caused by pressure on the trachea If death does not take place during the acute stage it is likely to result later from hemorrhage caused by ulceration into an artery or from pyemia produced by loosening of septic thrombi from one of the larger vessels of the neck

Otitis media one of the most common complications results from extension of the streptococcic infection in the throat to the middle ear and is characterized by rapidity of development The tendency of the streptococcus to destroy the drum membrane is responsible for the deafness which often results from scarlet fever Even when the drug is incised early the process may extend to the mastoid cells the lateral sinus the meninges or the brain

Nephritis —During the height of the acute febrile period there is only slight albuminuria without other evidence of renal irritation At times very severe throat complications are associated with a focal nephritis characterized by minute abscesses Typical nephritis develops during the second or third week of the disease but in exceptional instances may not appear until later It is found in about 10 per cent of all patients and in about 50 per cent of those with membranous angina Quite constantly preceding or accompanying the nephritis is the recurrent adenitis

Postscarlatinal nephritis is of three types—the mild the usual and the acute In a large percentage of the *mild cases* with sequelae affecting the throat and cervical glands the urine will show albumin and a few casts and at times even a few erythrocytes can be found There are no clinical signs of renal insufficiency except transient edema In the *usual cases* the symptoms are puffiness of the eyes edema of the lower limbs anorexia and pallor The urine may either contain only albumin and casts for a few days and then become hemorrhagic or may become suddenly dark reddish brown less abundant and loaded with albumin red blood cells and casts This condition may continue for a number of weeks before the nephritis gradually disappears or exceptionally may become chronic At any time during the acute course the kidneys may cease to function and signs of uremia appear In *acute cases* the course is extremely rapid The first indication of renal insufficiency may be a convulsion There is constant nausea and vomiting fever restlessness and convulsions The urinary secretion may cease entirely or the urine may be scanty bloody filled with casts and red blood cells and coagulate solidly on heating With proper treatment it is surprising how many children recover from this acute uremia Certain families seem especially vulnerable to nephritis but in spite of the fact that it is severe and often long continued there is a very good outlook for complete recovery.

McCollum found that nephritis became chronic in only 20 of 5000 cases

Arthritis —There are two types of scarlatinal arthritis the first a severe but fortunately rare complication is septic and suppurative being a manifestation of the generalized streptococcal septicemia which usually involves the larger joints and is often multiple the second and ordinary form the so called scarlatinal synovitis is very common in some epidemics usually appearing at the end of ten days in the wrists hands elbows, and knees It is manifested by redness some pain, and swelling due to synovial distention As a rule there is spontaneous recovery in the course of a week

Cardiac Complications —The cardiac complications which are most common in the severe toxic and septic cases result from marked fatty degeneration of the myocardium Sudden disappearance of the more or less intense rash usually indicates heart failure In the septic form malignant endocarditis may be associated with purulent pericarditis More frequently simple endocarditis develops which corresponds more closely to the rheumatic endocarditis

Complications of the Respiratory Tract — Purulent sinusitis is a frequent complication of septic fever Considering the severity of the throat infection it is surprising how seldom bronchopneumonia complicates scarlet fever The streptococcus of scarlet fever apparently has no tendency to localize in the lung Empyema is occasionally a complication

Involvement of the Central Nervous System —Osler, in discussing a series of 120 cases of infantile hemiplegia reports that 7 developed during scarlet fever *Meningitis* results either by direct extension from the ear or the accessory sinuses, or is caused by septic emboli endocarditis, or thrombosis In the more toxic conditions *acute mania* may develop As a postscarlatinal condition *encephalitis* is rare

Numerous cases of *gangrene* have been reported which involve small areas of the skin the hands or feet and occasionally an entire extremity The process is often fatal

Paronychia occurs frequently during desquamation Children and adults too constantly pull off the dead epithelium and many fissures are caused by rapid drying of the new skin Infection through these may give rise to a generalized *impetigo contagiosa*

Relapses, Recurrences, and Second Attacks —As a rule, one attack of scarlet fever gives immunity for life The fact that so many individuals who are exposed to the disease do not contract it suggests that much scarlet fever is unrecognized A patient having more than two attacks of so called 'scarlet fever' is very likely to be suffering from some other disease McCollum reports 15 relapses in 5000 cases thirty to thirty five days after the disappearance of the eruption Lichtenstein states that relapses are due to exogenous cross infection in patients who become immunized very slowly as indicated by a persisting positive Dick test after an attack

Relationship to Other Diseases —The relationship of diphtheria to scarlet fever in patients suffering with the latter is unsolved A recent study has demonstrated that immunity to diphtheria as shown by a negative Schick test may be lost during the course of scarlet fever In eight of 219 cases of scarlet fever in which the Schick test was negative it became positive during the course of the disease The mortality of the diphtheria complicating scarlet fever is about twice as high as that of the usual type

Diagnosis —The diagnosis must usually be made clinically Abrupt onset usually with vomiting rapidly rising temperature sore throat evidenced often by a follicular tonsillitis and marked reddening of the entire fauces the punctate rash on the hard palate followed in from twelve to twenty four hours by a finely punctate blush on the neck and chest which spreads gradually over the entire body, with the characteristic strawberry tongue and subsequent desquamation are so characteristic that it is easy to recognize the normal cases The difficulties are presented by the very mild and very severe forms In mild cases the insignificance of the general symptoms the inconsequential nature of the rash and the fact that it is patchy and seemingly due to local irritation rather than to systemic disturbance makes recognition very difficult A sore throat with a definite punctate rash on the roof of the mouth and soft palate associated with the scarlatiniform rash must

be considered evidence of scarlet fever The localization of the rash in the groins axillae and folds of the elbow may be of diagnostic aid in the mild cases Just as difficult of interpretation are the overwhelming toxemias without rash The rash on the roof of the mouth is usually present although it, too may be absent Careful search of the entire body surface may reveal small patches of erythema Equally difficult to recognize particularly in younger children is the septic streptococcal tonsillitis in which no rash is found even on repeated daily examination but which produces desquamation by the end of the second week

Of some value in differential diagnosis is the *Leede Rumpel phenomenon* which consists of spontaneous hemorrhage in the fold of the elbow after constriction of the upper arm with a rubber band This always occurs in scarlet fever The *Schultz Charlton phenomenon* is of pathognomonic significance it consists in the complete disappearance of the rash in from four to six hours in an area about the size of a dollar when the serum of an individual who has recovered from scarlet fever is injected intracutaneously Dick has shown that this always takes place when the serum is taken from an individual immune to scarlet fever even when there has been no previous attack

Differential Diagnosis—DERMATITIS EXFOLIATIVA—The differentiation of scarlet fever from dermatitis exfoliativa (scarlatiniforme) is difficult for this disease simulates very accurately the anginose as well as the cutaneous manifestations of scarlet fever Its onset is sudden and accompanied by fever and sore throat Desquamation of the tongue occurs and an eruption which is indistinguishable from that of scarlet fever develops and is followed by similar desquamation A primary attack of this disease is practically always mistaken for scarlet fever Its recurrent nature is the distinguishing feature Third or fourth attacks of scarlet fever are usually dermatitis scarlatiniforme

Measles—It is rarely difficult to distinguish measles from scarlet fever The simultaneous presence of both in the same individual is sometimes difficult to recognize At the onset of measles there is occasionally a scarlet like rash on the chest which precedes by some hours the typical eruption on the face the so-called preeruptive rash of measles' which may be difficult to distinguish from that of scarlet fever

RUBELLA—Differentiation of mild scarlet fever and moderately severe rubella is often difficult The rash of rubella may resemble in every way the fine punctate rash of scarlet fever Its distribution is characteristic, however since in rubella it is usually on the face where it is absent in scarlet fever The angina is usually less severe but the swelling of the posterior cervical glands more marked

The rash of *erythema subitum* may resemble very closely that of scarlet fever The characteristic appearance of the rash just after the fall of temperature distinguishes it very definitely from that of scarlet fever Desquamation is usually slight.

TONSILLITIS.—The differentiation from severe follicular tonsillitis with marked systemic reaction particularly in young children is practically impossible The differences in toxin production of various strains of streptococci may account for variations in the intensity of the rash

SMALLPOX CHICKENPOX—In smallpox and chickenpox there may be a prodromal rash which resembles in no slight degree that of scarlet fever The rapid appearance of the typical vesicular lesions usually renders diagnosis clear

DIPHTHERIA—The difficulty in distinguishing diphtheria from scarlet fever depends largely upon the type of membrane in the throat Although the two diseases may coexist and develop at the same time as a rule diphtheria occurs late in the course of scarlet fever The character of the membrane and its extent may help identification but only the demonstration of the *Corynebacterium diphtheriae* bacillus can establish diagnosis A membranous angina occurring late in scarlet fever is usually diphtheritic

RASH DUE TO DRUGS—The rash produced by *quinine* in certain susceptible individuals may be punctate in character resembling scarlet fever not only in itself but in the ensuing desquamation The absence of any throat symptoms and the taking of the drug are the differential features *Atropine* similarly may cause an eruption very comparable to that of scarlet fever The dilated pupils dryness of the mouth peculiar patchy blush of the face and absence of any throat

symptoms other than the dryness usually differentiate the two conditions *Aspirin* may produce an erythematous rash with the circumoral pallor The *iodides iodoform luminal* and *copaiba* may also produce a confusing rash

Anaphylactic Rashes —Most typical of the anaphylactic rashes is the *serum erythema* which appears a week or ten days after the injection of serum The rash may be morbilliform but is often typically scarlatinal in appearance and distribution It usually spreads over the entire body very much more rapidly than does the rash typical of scarlet fever The *ingestion of certain foods* (shellfish strawberries etc) may give rise to a rash indistinguishable from that of scarlet fever Knowledge of this idiosyncrasy together with complete absence of throat symptoms, usually establishes the diagnosis

In infancy and childhood the *erythemas caused by febrile disease* especially throat infections by *strenuous crying* by *irritating compresses bandages* or *ointments* or by *heat* may produce a skin picture more or less closely resembling that of scarlet fever The absence of other symptoms and a local cause for the rash usually makes the differentiation easy

Prognosis —The prognosis in scarlet fever is very uncertain The older the patient the better the prognosis The general conditions of hygiene seem definitely to influence the mortality McCollum s figures show for Boston over a period of twenty years a mortality rate varying from 1 to 6 per cent Hospitalization of scarlet fever patients in large cities has markedly reduced the number of deaths

The prognosis in the toxic type is usually grave, but is much better if antitoxin is administered early Hyperpyrexia cyanosis coolness of the skin with patchy erythema marked early swelling of the lymph glands and the tendency to bleed from the throat and into the skin are of very serious import especially when they occur early in the disease The second period of danger is during the second phase of the disease The prognosis for children who develop nephritis even if they have had convulsions is relatively good with proper treatment

Prophylaxis —Immediate isolation of every scarlet fever patient either at home or in a contagious hospital, is essential If the patient remains at home, individuals not directly exposed may be allowed their liberty if they show no symptoms at the end of eleven days The danger of carrying scarlet fever is such that the physician should always wear a gown roll the sleeves to the elbow during physical examination and thoroughly scrub his hands after leaving the patient

When the patient has recovered everything that can be washed should be thoroughly cleaned with soap and water Books and playthings must be burned Bed clothing should be boiled or fumigated in a confined space

Specific Prophylaxis —Susceptible individuals those manifesting a positive Dick test may be actively immunized by the subcutaneous injection of scarlet fever streptococcus toxin Dick advises the use of five injections of 500 2000 8000, 25 000 and 100 000 skin test doses of toxin at five- to seven-day intervals Although this amount is undoubtedly necessary for permanent immunity temporary immunity can be achieved by much smaller doses as is shown in the report of Keefer It would appear preferable to give an initial series of three injections of 500 2000 and 10 000 to 20 000 skin test doses followed after two weeks by a retest and to continue further immunization only in those who are still Dick positive As a general public health measure active immunization in its present form cannot be advised Active immunization is especially valuable in checking local outbreaks of scarlet fever in schools small communities etc and for the protection of those intimately exposed to the disease for limited periods of time Passive immunization by the administration of 2000 units of scarlatinal streptococcus antitoxin may be indicated in special instances Because it may have to be repeated at the end of two weeks a mixed convalescent serum is preferable for this purpose It is given intramuscularly in doses of 10 to 20 cc The general use of the antitoxin for prophylactic purposes is not advisable because of the relatively short duration of the protection and the low communicability of scarlet fever Children or others exposed to scarlet fever should be watched closely for sore throat

or other symptoms of the disease and the temperature should be taken twice daily

Treatment.—If rigid quarantine cannot be enforced at home patients should be sent to an isolation hospital Since in the early stages scarlet fever is not very contagious immediate isolation protects other members of the household In the home adequate isolation is practically impossible unless both patient and nurse can be quarantined in a room with adjoining bath The nurse should have special instruction in the care of infectious diseases and in aseptic technic Carpets rugs and hangings should be

As soon as desquamation starts the patient should be anointed each day with liquid petrolatum and washed every second day with soap If there is much itching menthol may be added to the petrolatum At the end of three weeks if the temperature has remained normal and no complications have developed, the patient may be allowed to get up one hour each day This period may be increased one hour a day thereafter

The urine should be examined daily during the first month and carefully examined once a week for at least two months after the

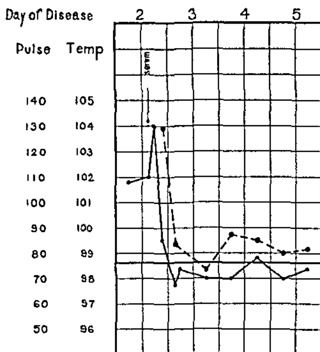

Fig 18—Scarlet fever treated with serum on second day of disease Immediate drop of temperature to normal Pulse curve is made of a series of dashes

removed and all unnecessary articles taken from the room Scarlet fever is a self limited disease so that in the mild cases general therapy alone is necessary The patient should be made as comfortable as possible and kept in bed for three weeks The bowels should be kept open and plenty of fluids consisting of fruit juices and water given in addition to the ordinary soft diet Pospischill who studied the effect of diet in a large series of carefully controlled cases was unable to determine that the incidence of nephritis was higher when a full diet was given than when milk only was allowed

illness because occasionally renal complications develop after an interval of several months At the end of four weeks if desquamation is complete and there are no discharges from nose mouth or ears the quarantine may be terminated The so called return cases are probably due to persisting infection in the nose and ears rather than to infection from scales

Specific Treatment—The first effective serum of this type was that produced by Moser in 1902 Scarlatinal antitoxin when given in adequate doses in the acute toxic phase of scarlet fever usually causes a

prompt abatement of the toxic symptoms and disappearance of the rash within twenty-four to thirty six hours There is frequently also a sharp drop in temperature and pulse rate and a diminution of the leukocyte count In addition, the antitoxin seems to lessen *the number of septic complications* and to diminish their severity when used during the acute toxic phase of the disease It appears, however to have no beneficial effect on postscarlatinal sepsis after the rash has faded The dose varies from 6000 to 80,000 units (1 unit is the amount of anti toxin necessary to neutralize 50 human skin test doses) depending upon the size of the patient and the severity of the disease The antitoxin is usually given intramuscularly but may be used intravenously in extremely toxic cases after desensitization which if properly carried out takes a considerable number of hours Severe anaphylactic reactions have been greatly reduced by the use of refined antitoxin Toomey calls at tention to the mild character of scarlet fever in the last decade and emphasizes the point that only after an epidemic with a high mor tality rate will it be possible to state defi nitely the value of the antitoxin Early ad ministration of the serum is essential for satisfactory results Recently there has been a revival in the use of convalescent serum in the treatment of the toxemia In many cities the development of serum centers which collect and distribute a pooled con valescent serum has made it widely avail able Given in the first forty eight hours in doses of 40 to 100 cc it produces results that often are as striking as are those which follow the administration of antitoxin It is best given intravenously but can be given intramuscularly It should be carefully warmed to body temperature and given over a period of about twenty minutes

The use of sulfonamides has been of great value in the reduction of the septic mani festations of the disease These drugs have no effect on the neutralization of the soluble toxin produced by the *Streptococcus scar latinae* but by inhibiting its growth they limit the toxin production and its local and general septic effects

Sulfanilamide or sulfadiazine should there fore be given at the earliest moment in ad dition to the serum in moderate and severe cases and alone in mild cases in which the initial temperature is less than 101.5° F The daily dosage recommended by Long and Bliss is ⅗ grain (0 04 Gm) per pound of body weight for the adult and 1 grain (0 065 Gm) per pound for the infant weigh ing less than 20 pounds (9 Kg) This dos age is given until the temperature has been normal for two or three days when it is gradually reduced to ⅖ grain (0 026 Gm) *per pound three times a day for the adult* and ⅕ to ³⁄₁₀ grain (0 013–0 018 Gm) per pound three times a day for the child Either sulfanilamide or sulfadiazine may be used preferably the latter because it has less tendency to produce toxic reaction

Symptomatic Treatment —For the almost constantly present cervical adenopathy the ice bag is used It is well to apply this early and not to wait until the glands are swollen The proper fitting of the ice bag particu larly in children, is essential Cold compresses, which can be used in the same way should be tied over the head rather than around the neck so as to reach the inflamed glands successfully They ought to be changed every two hours during the day and once during the night In the later stages par ticularly if cold is not well tolerated heat (a rolled up woolen cloth wrung out in hot water) applied in the same manner often relieves pain and causes rapid disappearance of the glandular swelling If the glands have begun to break down large hot compresses should be used and renewed every fifteen minutes for alternate hours Bullowa has suggested that tonsils so placed that the act of swallowing tends to milk their contents into the lymph channels should be removed even in the acute stage of scarlet fever This would seem to be indicated only in the exceptional case

It is desirable for older children and adults to gargle with a mild antiseptic solution every three or four hours For smaller chil dren or when gargling is painful irrigation of the throat with warm normal saline boric acid or dilute antiseptic solution (sev eral quarts) gives very apparent relief Such treatment is desirable in the moderate as well as in the most severe septic cases Ap plication of strong antiseptic solutions is contraindicated The nose should be kept clean and in case of crusting a few drops

of a 0 25 per cent preparation of menthol in liquid albolene inserted several times a day Cultures should be taken from the throat so as to exclude the possibility of diphtheritic infection and permit immedi ate administration of antitoxin if they are positive The ears must be examined daily even when there is no complaint As soon as there is an injection of the drum 7 per cent carbolated glycerin should be instilled into the ear filling the entire canal and a small ball of cotton saturated with the solu tion inserted in the canal as a plug As soon as there is bulging the drum should be widely incised If the discharge be sero sanguineous no irrigation is necessary, if purulent the ear should be washed with sterile salt solution or boric acid three times a day In young children tenderness and edema develop above the ear (subperiosteal abscess) instead of over the mastoid process The mastoiditis complicating scarlet fever should receive early operative treatment

For the toxic conditions with marked cyanosis caffeine in frequently repeated doses camphorated oil or digifolin given hy podermically is of some value

The mild nephritis usually needs no special treatment The patient should be kept in bed on a low protein salt free diet The indication for immediate treatment is the rapid development of uremia Removal of blood (250 cc in five year-old children 300 cc in ten year old children and 500 cc in adults) followed by an equal injec tion of salt solution usually brings the pa tient out of a state of coma and relieves the convulsions It may be necessary to repeat such treatment If the symptoms are due to edema of the brain the intravenous use of magnesium sulfate or hypertonic sugar solution will relieve the condition

BACTEREMIA

(*Septicemia*)

Definition —Bacteremia or septicemia is a feature of various infections and the only reason for discussing the subject separately is to direct attention to its significance in diagnosis and prognosis When bacteria are isolated from the circulating blood bacteremia is present Septicemia is frequently used synonymously with bacteremia al though it implies to some that bacteria are actually multiplying in the circulating blood It seems unlikely that bacteria ever multi ply in the circulating blood except under unusual circumstances such as in pre agonal states or when the focus of infection is intra vascular In any event the presence of micro organisms in the circulating blood should always raise the question of their source or their portal of entry

In general it can be said that bacteremia indicates a temporary loss of equilibrium be tween the local defense mechanism at the site of infection and the general immune and blood clearing mechanism of the body Bac teremia is of greatest value in diagnosis when symptoms of infection are present without localizing signs as in typhoid fever or undulant fever It is of the highest importance in prognosis when there is a recognized focus of infection with an associated

invasion of the blood stream, since bacteremia under these conditions indicates that there has been a breakdown of the normal defense mechanisms of the body

Etiology —The organisms that most commonly invade the blood are the hemolytic streptococcus, the staphylococcus the pneumococcus and the colon bacillus Less frequently one encounters such organisms as the gonococcus, meningococcus the *Bacillus mucosus capsulatus* or the influenza bacillus

Portal of Entry —The common portals of entry for bacteremia are the middle ear and mastoid process the skin the throat, and the genito urinary tract Less often the biliary tract and the bones are portals of entry The gastro intestinal tract is rarely a source of bacteremia except in cases of typhoid fever All these regions should be investigated for the possible source of infection in any patient with bacteremia It should always be remembered that infection of the endocardium may cause bacteremia without any other portal of entry being obvious

Pathogenesis —Bacteria enter the circulating blood directly by way of the lymphatics or the capillaries leading away from the original focus of infection Once they enter the blood stream the normal clearing mechanism of the body attempts to remove them as rapidly as possible This is accomplished in large part by the reticulo endothelial cells of the body which are located in the liver spleen, lymph nodes bone marrow and to a lesser extent in other tissues Once organisms have lodged in the various tissues of the body one of these things may follow they may serve as secondary foci of infection for bacteremia they may be destroyed without causing destruction of tissue or they may set up foci of suppuration (metastases)

Micro organisms may enter the blood stream from a focus of infection when an infected thrombophlebitis develops in the region of the infection or when the local defense mechanism is insufficient to prevent the spread of organisms They frequently enter the blood stream when the local defense mechanism has been ruptured such as following surgical incision and drainage or when the tissue is injured *in the neighbor*hood of an infection

It is well to remember, then, that the presence of bacteria in the circulating blood suggests an inadequate local defense mechanism at the site of the infection a thrombophlebitis, or several foci of infection

Morbid Anatomy —The changes in the organs seen postmortem vary with the type of infecting organism, the duration of the illness and the number of foci of infection When death occurs very rapidly—that is within a few days of the onset of the illness —there may be very few signs to indicate the cause of death There may be small hemorrhages in the skin or in the serous membranes The spleen is often enlarged and soft The liver may show some enlargement with cloudy swelling and focal areas of necrosis The kidneys may be swollen and studded with hemorrhages or small abscesses In hemolytic streptococcus or *Bacillus welchii* infections there may be evidence of excessive hemolysis of blood with hemoglobin staining of the tissues and jaundice

When the patient lives long enough and metastases develop abscesses and infected infarcts may be found in various organs such as the lungs, the kidneys the muscles or other organs

Symptoms and Signs —There are no distinctive symptoms or signs of bacteremia since identical clinical features may be present in infections with and without bacteremia The possibility should be considered in any patient who has fever without localized signs of infection or chills fever and sweats associated with evidence of one or more foci of infection Finally bacteremia should be suspected in all patients with symptoms and signs of infection who develop skin eruptions, arthritis splenomegaly jaundice multiple areas of bronchopneumonia or abscesses in the muscles or bones during the course of the infection Clues may be obtained if there is a history of a recent infection of the skin (furuncle infected wound) sore throat or otitis media Infections of the uterus following an abortion and infections of the genito urinary tract should be looked for The possibility of osteomyelitis should always be considered

The following points in the *clinical history* or *physical examination* may suggest bacteremia but they do not establish the diagnosis In any patient suspected of hav

ing bacteremia one should ascertain whether there have been infections in the past which might serve as a portal of entry Of particular importance are infections of the skin such as boils carbuncles paronychia or infected wounds infections of the throat middle ear or mastoid process infection of the genito urinary tract such as pyelitis pelvic inflammatory disease or gonorrhea previous operations for infections such as extraction of teeth catheterization of the bladder or surgical incision and drainage of an abscess or any other infection and previous pulmonary infections

In the *physical examination* the following features suggest the presence of a bacteremia

1 Continuous or irregular fever with or without chills and sweats but without any local signs of infection In all such patients a blood culture should be made

2 Hemorrhages into the skin conjunctivae or mucous membranes

3 Acute monarticular or polyarticular arthritis or pain in the bones

4 Signs of pulmonary infarction or diffuse bronchopneumonia

5 Signs of endocarditis that is evidence of valvular heart disease splenomegaly or embolic phenomena

6 Signs of pelvic infection in women or prostatic or urinary tract infection in men

If any of the above symptoms and signs are associated with a progressive anemia jaundice and leukocytosis the possibility of a bacteremia is much more suggestive

When there is any question of a bacteremia being present a blood culture should be made at once

The *onset* of bacteremia may be abrupt with chills and fever irregular or continuous Some patients are perfectly clear mentally while others soon show delirium Headache often with vomiting and meningismus is common and in some forms of sepsis meningitis is an outstanding feature This is especially true of cases of pneumococcus bacteremia and of streptococcus bacteremia following otitis media and mastoiditis

Skin eruptions are frequent and important in diagnosis Petechial hemorrhages into the skin and conjunctivae are most often encountered Erythematous and even papular and vesicular eruptions are not infrequent Jaundice due to blood destruction and depressed liver function is an occasional outstanding feature and abscesses of the skin and subcutaneous tissues are not infrequent

Pains in the joints and true arthritis are common manifestations of streptococcus meningococcus and gonococcus bacteremia

The *bones* and *muscles* should be examined for evidence of infection such as osteomyelitis or abscesses of the muscles

The *lungs* may show multiple areas of bronchopneumonia or pulmonary infarcts and empyema Bronchopneumonia is common in hemolytic streptococcus and staphylococcus sepsis and pulmonary infarction is especially frequent in thrombophlebitic types of sepsis arising in the pelvic veins or cranial sinuses Infarcts are also frequent in thrombophlebitis of the tonsillar and renal veins

Pericarditis is occasionally encountered when there is an infection in the adjacent lung or heart

The *heart rate* is usually accelerated and when endocarditis is present a murmur is usually but not always present

The *abdomen* may be distended and anorexia and vomiting can be prominent features The spleen is generally enlarged but it is not always palpable during life

Blood Examination—In most patients with bacteremia there is a rapidly progressing anemia with leukocytosis A normal or depressed leukocyte count is by no means uncommon but there is generally an increase in the polymorphonuclear leukocytes An increase in the icteric index is found when hemolysis is progressing at a rapid rate

Urine—Albuminuria is present in most cases and hematuria and pyuria are less frequent Occasionally one can isolate the same organism from the urine as from the blood

Diagnosis—The diagnosis of bacteremia is established by culturing micro organisms from the circulating blood The blood should be withdrawn under sterile conditions and inoculated in flasks of broth as well as in melted agar for pour plates When the question of anaerobic bacterial infection arises the blood should be cultured under conditions suitable for growing anaerobic organisms

Prognosis—The outlook in patients with bacteremia is always grave and the fatality rate in patients with infections associated with bacteremia is always higher than in those without it Factors influencing prognosis when bacteremia is present depend upon the summation of such factors as the site of the primary focus of infection the age of the patient the species of microorganism, the presence of associated debilitating disease the accessibility of foci of infection for surgical drainage and the type of treatment All these factors must be taken into account in assessing the prognosis of any patient with bacteremia

Treatment—The treatment of patients with bacteremia must be directed along three lines general supportive and symptomatic treatment, the use of specific measures that aid in the clearing of the blood and focalizing the infection, and the removal or drainage of foci of infection

General and Symptomatic Treatment—All these patients should receive expert nursing care The food intake should be increased insofar as possible in order to maintain the nutrition status of the patient and fluids should be forced so that the twenty four hour urinary output is at least 1500 cc Blood transfusions of 500 cc each should be given to all patients who develop an anemia below 70 per cent hemoglobin (10 5 Gm per 100 cc) Sedatives should be given for headache and the skin should be kept clean and in good condition

Specific Measures that Aid in Clearing the Blood of Organisms and Focalizing the Infection—CHEMOTHERAPY—Since the introduction of the sulfonamides the fatality rate in patients with bacteremia has decreased, so that all such patients should receive some form of sulfonamide therapy The drug of choice at present in the treatment of bacteremia regardless of its cause is sulfadiazine largely because it is pleasanter for the patient to take and there are fewer side reactions such as anemia leukopenia drug fever and skin eruptions Renal complications are less frequent than when sulfapyridine or sulfathiazole is given but they will occur unless the fluid intake is forced so that the daily urinary output is at least 1000 to 1500 cc In a few patients renal injury follows the administration of sulfadiazine in spite of an adequate fluid intake When sulfadiazine is not available the drug of choice is sulfathiazole These drugs should be given so that the concentration in the blood is at least 10–12 mg per 100 cc for sulfadiazine and 8–10 mg per 100 cc for sulfathiazole

This can usually be accomplished by an initial dose of 4 Gm (60 gr), followed by doses of 1 Gm every four hours When this dosage fails to produce maximal concentration in the blood it must be increased

If patients are unable to take the drug by mouth, the sodium salt of sulfadiazine or sulfathiazole may be given intravenously, dissolved in sterile distilled water in a concentration of 5 Gm in 100 cc When the drug is given intravenously one must be certain that the fluid balance is such that the twenty four hour output of urine is at least 1000 cc

For children, the daily dosage should be arranged so that 0 2 Gm per kilogram of body weight or 1.5 grains per pound should be given during the twenty four hour period

Serum Therapy—Serum treatment is of value in pneumococcus and meningococcus bacteremia but it is needed less often now than before the introduction of the sulfonamides Some success has been reported following the use of anti staphylococcus serum (Julianelle) in cases of staphylococcus sepsis Other sera are of little value in the treatment of bacteremia

Removal or Drainage of Foci of Infection—The removal or drainage of foci of infection is important in any patient with focalized infection and bacteremia but one must be certain that the infection is well localized and that it can be drained without rupturing the local defense mechanism That is to say, incision should not be carried beyond the wall of any abscess These are problems that must be handled by a competent surgeon

FOCAL INFECTIONS

The term 'focal infection was coined by Frank Billings who, in his classic contribution "Chronic Focal Infections and Their Etiologic Relations to Arthritis and Nephritis' was really the originator of the theory of focal infection Focal infection may be defined as a localized infection which presumably produces symptoms in other parts of the body and in which there is usually no demonstrable bacteria in the blood stream This distinction however cannot always be made For example one of the commonest of the focal infections is that produced by the gonococcus in the posterior urethra or in the prostate gland with secondary involvement of the joints in the form of gonococcal arthritis In such a condition the gonococcus has of course reached the joint by way of the blood stream but in the vast majority of cases this fleeting bacteriemia cannot be demonstrated by blood cultures

At the present time nearly thirty years after the publication of Billings article focal infection has come to occupy a very important place in the activities of medical and surgical practice and the various specialties Many thoughtful physicians however who originally accepted the theory of focal infection with enthusiasm have watched with interest and some trepidation its rapid development in the various fields of medicine and are now wondering if the time has not arrived for a revaluation of the theory Many students today question seriously its validity and some are quite willing to throw it completely overboard This is particularly true in Europe where the idea of focal infection has never met with enthusiastic acceptance But even in America many practitioners are becoming a little wearied of the theory which has been accepted as if it were an established fact

Etiology.—The original theory of focal infection as propounded by Billings was to the effect that foci of infection in the tonsils teeth sinuses and other sites may produce disturbances in distant parts of the body such as the joints or kidneys by means of a toxin which presumably circulates through the blood stream Such a toxin, however has never been demonstrated

Foci of infection have been assumed to play a role in many diseases such as arthritis iritis rheumatic fever nephritis heart disease and bronchiectasis It is probably in connection with rheumatoid arthritis however that the theory has been most intimately associated In 1938 the writer in collaboration with D M Angevine analyzed 200 cases of rheumatoid arthritis and found that definite foci of infection existed in only 20 per cent of them It is quite obvious that the incidence of focal infections in patients with arthritis and other systemic diseases varies widely depending on the type of patient studied For example foci of infection would be quite prevalent in patients selected from a large city hospital while the same number of patients from private practice would reveal comparatively few

By far the commonest micro-organism involved in focal infection is the streptococcus either the *Streptococcus haemolyticus* or the *Streptococcus viridans* the gonococcus staphylococcus and pneumococcus come next in order The colon bacillus is not an infrequent cause of focal infections in the abdominal cavity or in the genito urinary tract It is axiomatic of course that all infections have an original portal of entry through which micro-organisms gain access to the body The portal of entry may be the site of a very fleeting infection such as an acute coryza or influenza or it may be that of a chronic focus such as a chronic sinusitis or apical abscess of a tooth

Morbid Anatomy—A focus of infection may be localized in any part of the body but most commonly it occurs in the tonsils or about the teeth Foci in the tonsils are much more prevalent in children and adolescents while root abscesses about the teeth are usually but not always discovered in elderly persons Other important locations for focal infection are the accessory nasal sinuses the genito urinary tract, the

gallbladder and occasionally the appendix In the intestine itself, ulcerative colitis and diverticulitis may produce symptoms in the joints and other parts of the body Bronchiectasis occasionally acts as a focus of infection

Symptoms—Many conditions have been suspected of being caused by foci of infection The most common are subacute and chronic arthritis of the infectious type and rheumatoid arthritis however, the kindred rheumatic conditions, such as myositis, fibrositis and neuritis have also been included Acute glomerular nephritis and inflammatory lesions of the eye such as iritis, uveitis keratitis and choroiditis have been attributed to focal infection Other less common diseases which may be related to foci of infection are erythema nodosum phlebitis, perinephritic abscess and possibly pyelitis Conditions which are much more plausibly attributed to focal infection are general debility loss of weight secondary anemia fatigue and muscular weakness Furthermore a focal infection may lower the resistance to a disease of which it is not the cause, and removal of foci may therefore be an important measure in the treatment of chronic systemic diseases such as tuberculosis syphilis and diabetes

Diagnosis—The diagnosis can often be made by simple inspection For example, highly infected tonsils present an unmistakable picture However there have been a great many instances of presumptive diagnoses in respect to focal infection It is very difficult at times to decide whether tonsils are actually infected, or whether they have undergone a simple hyperplasia A frankly suppurative sinusitis is easily recognized but low grade infections of the sinus are often identified with considerable difficulty The same is true of root abscesses about devitalized teeth In many cases the decision of whether a root abscess actually exists is difficult to arrive at even after the most careful x ray study The demonstration of pus or pus cells and the cultivation of pathogenic bacteria from a suspected focus will always do much to confirm the diagnosis of a genuine focus of infection

Prognosis—Removal of a focus of infection may be followed by relief of remote symptoms Unfortunately this is not always the rule The improvement may be rapid or gradual and is sometimes preceded by an exacerbation of the symptoms immediately following the removal of the focus Prediction of improvement should be made with care and promise of cure should not be held out in diseases of which the cause is still unknown

Treatment—An obvious focus of infection should usually be removed provided the health of the patient permits such removal without too much risk of disaster If the tonsils are acutely inflamed it is better to wait several weeks until the activity of the infection has subsided before removing them The same applies to all operative procedures in the presence of the various acute infectious diseases especially rheumatic fever If many teeth are infected only one or two should be extracted at a time Very anemic patients should receive a transfusion of blood before operation In rheumatoid arthritis it may be wise to remove tonsils which are diseased and to treat active sinus infections not because of their proven etiologic relationship to the arthritis but because anything which improves the health of the patient will probably be of some benefit in overcoming the arthritis The decision regarding removal of a focus of infection must usually be made eventually by the internist after consultation with the laryngologist and the dentist

STAPHYLOCOCCUS INFECTIONS

INTRODUCTION

STAPHYLOCOCCI are the commonest cause of pyogenic infections All forms of staphylococci except the *Staphylococcus aureus* are

relatively nonpathogenic By appropriate cultural methods however, and possibly in the human body the usually innocuous forms such as *S albus* and *S citreus* may be converted into the pathogenic *S aureus* Pathogenic strains produce a soluble toxin *leukocidin* a hemolysin a tissue necrotizing toxin plasma coagulase, and the so-called Duran Reynals factor,' an agent which enhances tissue permeability and infection Julianelle and his co workers have shown that staphylococci may be divided into types A' and 'B on the basis of immunologic and chemical differences between the intracellular polysaccharides elaborated by the respective organisms They found also that Type A strains ferment mannite and are pathogenic while the non mannite-fermenting Type B strains are not They demonstrated that the sera of patients suffering from prolonged general infection and of those finally recovering from infection contained precipitins for the specific carbohydrates It should be emphasized that strains of *S aureus* after eight to twelve hours incubation often appear almost white but develop the typical yellow pigment on exposure to the sun or to diffuse daylight

Although man is generally prone to staphylococcus infection there is a great variation in his susceptibility to the disease Trauma malnutrition agranulocytosis diabetes diseases of the kidneys and blood vessels filth friction of the skin and possibly variations in the acid reaction of the skin itself are important factors

Staphylococci are often found in symbiosis with streptococci pneumococci and influenza bacilli

While pure staphylococcus infection tends to remain localized at the site of entrance as in the skin sinuses middle ear tonsils teeth and lungs metastatic infection of the meninges heart pleura kidney bones joints and regional lymph nodes not infrequently occur and in severe infections the blood stream is invaded

HENRY T CHICKERING

FURUNCULOSIS

Definition.—Furunculosis is an infection of the skin characterized by the presence of multiple furuncles or boils appearing simultaneously or in successive crops

Etiology—Almost all furuncles are due to the entrance of *Staphylococcus aureus* into the hair follicles or skin

Symptoms—The individual furuncle may appear as a painful indurated elevated area of erythema which gradually increases in size for about four to seven days Then softening takes place and a small central yellowish spot appears which finally discharges pus This small opening enlarges until the softened slough can be evacuated after which healing rapidly takes place A boil may first appear as a very superficial infection about a hair follicle The vesicular head soon discharges and healing takes place or the infection may steadily penetrate into the deeper layers of the skin and go through the evolution just described If the boil is situated in an area where the skin is firmly attached to underlying fascia the lesion is clearly circumscribed and accompanied by pain If situated where the skin is freely movable there may be widespread edema of surrounding tissue and very little pain connected with the boil itself

Furunculosis usually develops through dissemination of the staphylococci discharged from the original infection to other parts of the body The prevention of this spread often presents great difficulty on account of the location of the original lesion in the axilla groin or vulva

Other factors such as malnutrition diabetes or conditions accompanied by itching contribute to one s susceptibility to staphylococcus infection Dirty fingers filth friction and contaminated clothing especially sweaters are important factors in the production of furunculosis

Morbid Anatomy—With the onset of infection there is a diapedesis of white blood cells to the infected area thereby localizing the infection In rare instances a single innocent looking boil may be followed by a general septicemia and death although usually the leukocyte reaction forms an effective barrier to a general infection Due to the production of soluble toxins and lytic agents a necrotizing action is produced in the center of the furuncle which leads to the formation of a slough composed of pus glandular and perifollicular tissue The slough grad

ually liquefies, separates from the surrounding tissue, and upon receiving sufficient drainage is evacuated and replaced by granulation tissue

Diagnosis —Usually there is no difficulty in the diagnosis The presence of pain and the subsequent evolution of the furuncle distinguish it from impetigo contagiosa Carbuncles are characterized by multiple points of suppuration whereas the furuncle has only one 'head"

It is important before incising a boil to examine microscopically a drop of the purulent secretion obtained by gently nicking the purulent spot (not squeezing) in order to establish the presence of staphylococci since early incision of an anthrax pustule greatly increases the danger of general dissemination of the infection and death

Prognosis —The prognosis in furunculosis depends a great deal on treatment The average duration of a single boil is one or two weeks but if care is not taken to prevent spread of the infection to new sites, it may run a prolonged course In rare instances general septicemia or pyemia may lead to a fatal termination

Treatment —The most important single factor in the treatment of furunculosis is to prevent dissemination of the infecting organism In severe cases the patient should be put to bed After a careful cleansing of the body, care should be taken not to rub the skin with a towel and separate towels should be used for drying the infected areas After the initial bath the tub or shower should be prohibited Often this procedure alone stops the succession of boils If the furuncles are localized in the axillae or on the perineum or vulva careful shaving with a sterile razor followed by a moist dressing of 1 5000 bichloride of mercury will protect the skin from reinfection Ethyl alcohol (15 per cent) or extract of hamamelis is often very effective Seventy per cent ethyl alcohol may be used for cleaning the oozing areas but its prolonged use as a dressing is irritating to some skins

As the boil matures a small opening may be made at the point of the suppuration taking care not to use force in expressing the contents and making as small an incision as possible to avoid opening of new avenues of infection The application of tincture of iodine into the sloughing area will assist in the separation of the slough Once the boil discharges the physician should exert all his ingenuity to prevent the spread of the infection The pus should be removed by patting with a sponge wet in alcohol not by rubbing If adhesive tape is used it should be removed by a solvent solution such as benzine to avoid abrading the skin and thus offering a new site for infection It is very important not to traumatize a furuncle situated on the nose or upper lip To do so may lead to a fatal bacteremia and meningitis It is in these cases that x ray therapy has proved very effectual

Staphylococcus aureus vaccine either stock or autogenous is sometimes of value in preventing the development of new furuncles Application to the skin of 5 per cent sulfathiazole or sulfadiazine ointment is also valuable in preventing fresh infections

HENRY T CHICKERING

CARBUNCLE

Definition —A carbuncle is an acute local inflammation of the deeper layers of the skin leading to the formation of multiple purulent openings and extensive slough

Etiology —The etiology of carbuncle is essentially that of a furuncle But due either to the special characteristics of the *Staphylococcus aureus* or to the lack of resistance of the patient, the infection spreads laterally through the skin producing a honeycomb like necrosis beneath the surface before the multiple purulent exits are formed

Pathology —The pathology of carbuncle is like that of furuncle in its incipiency It is not known whether the intense induration occludes the blood vessels of the area producing slough or whether certain strains of staphylococci produce hemolyzing and necrotizing substances in unusual abundance to effect this honeycomb type of slough Certain it is that in some cases where there appears to be every opportunity for free drainage from several surface exits the process continues to spread rapidly until the whole boggy purulent area is freed from the underlying fascia

Symptoms —The onset of a carbuncle may simulate a simple furuncle but often

constitutional symptoms such as fever chilly sensations and general malaise are more noticeable If a furuncle is traumatized by squeezing the area of induration may spread and become brawny and dark red in color, the infection spreading not only on the surface but deeper into the subcutaneous tissue After several days necrosis of the deep parts of the skin and the subcutaneous tissue takes place The skin itself thins out at several points showing yellowish red pus and finally a small amount of purulent fluid is discharged

The whole indurated area eventually becomes a mass of sloughing tissue which separates out, leaving a deep ulcer When complicated by bacteremia repeated chills and sweats ensue and death may take place

Diagnosis—Carbuncle differs from furuncle by its more extensive area of erythema and induration and by its multiple purulent heads Here again it is important to definitely rule out anthrax infection before instituting surgery

Prognosis—In the aged or debilitated or those suffering from diabetes or diseases of the kidneys and blood vessels the prognosis is always grave In such cases the occurrence of septicemia or septic embolic infections is not infrequently a cause of death

Treatment—The treatment is directed against the underlying constitutional condition as well as the local infection In diabetes measures to control the glycosuria and hyperglycemia should be vigorously instituted In those suffering from wasting diseases and anemia small repeated blood transfusions are useful In the milder carbuncular infections hot poultices of flaxseed or witch hazel often help to relieve pain and hasten the development of the multiple purulent heads When these simple measures are not followed by definite improvement free drainage should be instituted by a surgeon Usually this requires a crucial incision extending beyond the area of induration and a thorough freeing of the infected area from the underlying fascia During the past few years the results of x ray therapy in carbuncle have been very promising For about four hours after treatment there is increased swelling and pain followed shortly by marked decrease in symptoms The purulent heads coalesce and drainage becomes free In some cases a second or third exposure is necessary following which rapid softening of the infected area and healing takes place without surgical intervention

STAPHYLOCOCCUS BACTEREMIA

(*Pyemia*)

Staphylococcus aureus bacteremia results when the staphylococcus is either constantly or intermittently circulating in the blood stream

Etiology—Where resistance to infection is low or the invasiveness of the particular strain of staphylococcus is high the blood conveys the germs from the local lesion to regions far distant from the primary focus Invasion of small numbers of bacteria from the focus are often taken care of and eliminated from the blood by the liver without metastatic infection But if the mass of infection is great or if the primary lesion is so situated that the lungs endocardium brain bones or urinary tract first receives the organisms metastatic abscesses frequently develop If the primary focus and the metastatic foci are properly drained the bacteremia clears up The continued presence of bacteremia indicates insufficient drainage

Morbid Anatomy—Infected emboli or free bacteria may be carried to any organ of the body and in staphylococcus infections multiple abscesses may develop Infection is prone to occur in regions whose blood supply has been damaged by previous infections as at the site of a chronic endocarditis Septic infections may develop on the heart valves as well as in the spleen kidneys or brain

Symptoms—The symptoms of staphylococcus bacteremia vary from a relatively mild febrile condition suggesting influenza tuberculosis typhoid or rheumatic fever to a very fulminating infection in which death supervenes in three days Occasionally an innocent looking pustule on the scalp or a furuncle on the nose or upper lip may terminate fatally in such a short time The fever may be intermittent or constant, often there are drenching sweats The blood usually shows a well marked polynuclear leuko

cytosis but occasionally in the fulminating cases white blood counts under 1000 and an almost complete absence of polymorphonuclear cells is seen

Staphylococcus meningitis may develop from an old chronically infected accessory sinus of the nose One patient whose symptoms on the first day suggested influenzal infection was dead four days later, the spinal fluid and blood showing pure *Staphylococcus aureus* infection In this case no primary focus was found at autopsy

When the endocardium is the site of the principal infection definite changes in the intensity and pitch of the heart murmurs are a very significant symptom In children staphylococcus pericarditis while uncommon, should always be borne in mind, for it is in these cases that brilliant results have been obtained from surgical drainage

Occasionally in furunculosis a small staphylococcus abscess may develop in the lungs It is often accompanied by localized pain, and recovery may take place without surgical intervention In other cases, a large lung abscess or an empyema may supervene and require surgical intervention

In staphylococcus bacteremia the possibility of perinephritic abscess should always be borne in mind If the kidney is the seat of septic emboli the presence of blood in the urine is a suggestive sign Infarcts of the spleen are accompanied by pain and palpable enlargement of the organ Metastatic infections of the eyes muscles and genitalia are rare though not infrequently the prostate is the seat of primary or metastatic infection The bones and joints are often implicated in *Staphylococcus aureus* infections Infection of the skin from scratching particularly in chickenpox may be followed by osteomyelitis of bones far distant from the site of the original furuncle Pain in the affected bone or joint and the presence of a healing furuncle suggest the diagnosis

Diagnosis—In febrile conditions the cause of which is not obvious the practice of making blood cultures is the most important aid in diagnosis Preferably the blood should be taken when the temperature is elevated Twenty cc should be removed from the arm vein and planted in plain broth and agar In this way an indication of the intensity of the bacteremia can be obtained Repeated cultures should be made if the first proves to be sterile The presence of *Staphylococcus aureus* in the blood rules out other infections, such as typhoid fever, rheumatic fever, pleurisy miliary tuberculosis, streptococcus endocarditis, malaria and trichiniasis

Prognosis—In fulminating *Staphylococcus aureus* infections the mortality rate is almost 100 per cent In less severe infections the death rate depends on the site of the metastatic lesions and whether adequate drainage can be obtained

Treatment—The treatment of staphylococcus pyemia is essentially surgical, although adequate sulfa drug therapy may prevent additional foci of infection Every effort should be made to secure satisfactory drainage If the infection has been of long standing or if the patient shows a secondary anemia of 60 per cent or more repeated small blood transfusions are helpful

Julianelle has recently reported on the treatment of staphylococcus bacteremia with a processed staphylococcus Type A rabbit serum with very encouraging results The careful bacteriologic and biochemical investigations on which this clinical study was based make the further use of this serum particularly desirable

STAPHYLOCOCCUS AUREUS PNEUMONIA

Definition—*Staphylococcus aureus* pneumonia is an acute specific infection of the lungs characterized by the formation of multiple abscesses

Etiology—As early as 1889 Netter and later Fraenkel and Leichtenstern described an influenzal bronchopneumonia accompanied by the formation of abscesses from which the *Staphylococcus aureus* was isolated in pure culture

Infection of the lungs takes place by direct extension of the bacteria from the upper respiratory tract when conditions favorable to the growth of staphylococcus are present Strong support for this point of view is offered by the fact that bacteria found in the normal nose and throat such as hemolytic streptococcus pneumococcus *Haemophilus*

influenzae and others are occasionally seen growing in symbiosis with *Staphylococcus aureus* in this disease Moreover in *Staphylococcus aureus* pneumonia, metastatic infections in the bones joints and kidneys are most unusual in contradistinction to the picture seen in staphylococcus infections of the skin In staphylococcus pneumonia the disease spreads by direct extension instead of by the blood stream and lymphatics

The disease occurs most commonly in pandemics of influenza Chickering and Park reported 153 cases of postinfluenzal staphylococcus pneumonia in a series of 312 fatal cases as determined by postmortem lung cultures The disease also occurs endemically The author has seen 18 cases in private practice in a series of 500 cases of pneumonia of all types over a period of fifteen years Lyon has noted the disease in 9 6 per cent of cases of bronchopneumonia in children In 211 cases of primary atypical pneumonia Cole reported that 9 per cent were associated with *Staphylococcus aureus*

Morbid Anatomy—The primary catarrhal inflammation and edema of the respiratory mucous membrane with the tendency to hemorrhage into the walls of the bronchioles so characteristic of influenzal infection offers a favorable medium for the growth of the staphylococcus In the very fulminating infections lasting only five or six days from the onset of the influenza the lung shows such intense hemorrhagic infiltration that the cut surface resembles that of an acute splenic tumor If the disease is less acute multiple abscesses of all sizes depending on the duration of the disease are seen The distribution of the lesions is bronchopneumonic in character the dependent portions of the lung being most frequently involved There may or may not be any pleural exudate Examination of the surface of the pleura shows in addition to petechiae small yellowish white spots pinhead in size which prove to be minute abscesses The rupture of these subpleural abscesses is responsible for the frequent occurrence of single or multiple collections of pus in the pleural cavities Where the disease has lasted seven or more days the cut surface of the lungs shows myriads of minute abscesses some coalescing to form larger foci Microscopic sections of the lung show intense congestion with rupture of the alveolar walls and exudation of serum and red cells into the alveoli When stained for bacteria typical clusters of gram positive cocci are seen

Symptoms—The onset of *Staphylococcus aureus* pneumonia is almost always insidious and rarely accompanied by the chill and localized pain of lobar pneumonia If it develops as a complication of influenza the temperature rises instead of disappearing by the fourth day and the patient becomes gravely ill The expression is anxious and a peculiar cherry red cyanosis develops At this period signs of pulmonary involvement are extremely scanty perhaps nothing more than slightly decreased resonance and diminished breath sounds at the bases and a few fine moist rales Herpes labialis is uncommon The mind remains surprisingly clear throughout the disease

Occasionally pleuritic pain is complained of but this is not usual In the latter stage of the disease profuse sweating may take place The fever on the whole is high ranging between 104° and 106° F with frequent remissions The pulse is relatively slow at the onset and in only a few cases does it rise above 120 until just before death The quality of the pulse is usually small and weak Respirations range between 24 and 36 and in some cases rise to 50 or 60 without much apparent discomfort

The severity of the symptoms may increase with the most startling rapidity and death may follow in two or three days the signs in the chest being those of a patchy bronchopneumonia Of the cases seen in the influenza pandemic of 1917 12 died between the first and fifth day and 73 between the sixth and tenth day A few cases live to develop large pulmonary abscesses and suppurative pleurisy

Diagnosis—The sputum in staphylococcus pneumonia unlike the rusty tenacious material of pneumococcal infections is often friable purulent and of a dirty *salmon-pink* color Typical sputum however is not always obtainable and the patient may produce only greenish yellow purulent material which on direct smears and cultures shows the staphylococcus as the predominant organism

If sputum containing the staphylococcus is streaked on glucose free blood agar plates

the colonies appear as opaque round, shiny disks surrounded by a wide zone of hemolysis after eighteen hours' incubation On removal from the incubator, the colonies may appear white, but if the plates are allowed to remain a few hours in sunlight the yellow pigment appears

In the severe cases the staphylococci invade the blood stream, about 50 per cent of the writer s patients had positive blood cultures In spite of the high percentage of blood cultures only one patient developed meningitis In most cases of staphylococcus pneumonia death takes place before complications have an opportunity to manifest themselves In the few that survive staphylococcus empyema pericarditis and massive lung abscess are the common sequelae

Many cases of staphylococcus pneumonia show a marked leukopenia This may be due to the influence of the primary influenza infection for it has been noted that where the disease is less severe and of longer duration a well marked polymorphonuclear leukocytosis is present

The x ray is of great assistance in demonstrating the scattered patchy areas of bronchopneumonia and the presence of fluid in the pleural cavities or the pericardial sac

Prognosis —The mortality rate in *Staphylococcus aureus* pneumonia is extremely high (from 70 to 80 per cent die in the acute phase of the disease) although increasing experience with the use of sulfonamides has made the prognosis less grave In a few cases small lung abscesses demonstrable by x rays resolve without surgical intervention More often there eventuates a staphylococcus infection of the pleura or pericardium which yields to adequate surgical drainage

Treatment —Although treatment of the fulminating cases of *Staphylococcus aureus* pneumonia is usually ineffectual several observers have reported good results from the use of sulfathiazole and sulfadiazine In addition the anti staphylococcus Type A rabbit serum of Julianelle should be used if available Recently a few cases treated with penicillin have been reported with astonishingly good results The oxygen tent may aid in tiding the patient over the acute stage of the disease Surgery may be necessary in the cases which develop empyema although five of six cases of Finland treated with sulfa drugs required only repeated aspirations

GONOCOCCAL INFECTIONS

Definition —The term gonococcal infections designates maladies which have a common etiologic basis but are diverse in their clinical manifestations The individual signs and symptoms of the several diseases caused by the gonococcus (*Neisseria gonorrhoeae*) are varied and depend to the greatest extent upon the locations in the body of the offending infection The numerous clinical entities are identified therefore by reference to the tissues or organs which are principally involved

Historical —The gonococcus first of the group of gram negative cocci to be described was identified in 1879 by Neisser who observed its special characteristics in urethral pus Artificial cultivation being difficult, however the *significance of the species in the etiology* of diseases of general medical interest (other than genital infections) did not become firmly established on a sound bacteriological basis until a decade or more later In 1893 Rendu first cultivated the organisms from exudates derived from acute arthritis Thayer and Blumer in 1897 first isolated gonococci antemortem from the blood stream of a case of endocarditis

Within the scope of gonococcal infections encountered in internal medicine the following is a list of diseases which have been described and which have been proved or have been considered on reasonable grounds to be of neisserian origin

1 Arthritis bursitis tenosynovitis myositis osteitis periostitis, chondritis perichondritis
2 Endocarditis pericarditis, myocarditis (abscess formation), thrombophlebitis
3 Cutaneous manifestations hyperkeratosis simple erythema erythema nodosum pustular bullous and hemorrhagic exanthemata condylomata, keratodermia blennorrhagicum
4 Meningitis myelitis meningomyelitis polyneuritis sciatica psychoses and neuroses
5 Laryngitis tonsillitis otitis media adenitis pneumonia (usually embolic) parotitis thyroiditis
6 Acute glomerular nephritis, pyelonephritis and pyonephrosis
7 Proctitis and peritonitis
8 Septicemia and infected surgical wounds

(Ophthalmic and genito urinary diseases are not included)

Etiology—The gonococcus belongs to a group of micro organisms classified as Neisseria The two members of the group most commonly encountered in infection in man are *Neisseria gonorrhoeae* (gonococcus) and *Neisseria meningitidis* (meningococcus) A third member *Neisseria catarrhalis* is rarely important in the production of disease However since it is a common inhabitant of the upper respiratory tract differential bacteriologic diagnosis may be important in determining the cause of diseases where cultures of nose throat or sputum are employed

Members of the Neisseria group are gram negative cocci which are commonly seen in pairs (diplococci) Morphologically they are characterized by the fact that the adjacent sides of the oval pairs are flat or concave in contrast to the elongated structure of other diplococci such as pneumococcus The oval form with flat abutting sides is so typical that they have been commonly described as biscuit shaped or kidney shaped diplococci In these shapes and contained within leukocytes they are most commonly seen in stained smears of exudates derived from patients

The gonococcus is an aerobe (usually obligate) and is relatively fastidious in the growth requirements necessary for artificial cultivation They grow poorly or not at all in plain meat infusion broth or agar Of numerous media advocated those to which some protein of the body is added such as serum or ascitic fluid usually serve as the most satisfactory The use of atmospheres containing increased per cent of CO_2 has been advocated by some bacteriologists However others have failed to confirm this finding and refer to factors relating to pH and degree of humidity and prevention of evaporation as possible important elements which require control in evaluating the significance *per se* of the CO_2 concentration of the media

Each of the three gram negative cocci just discussed is with greatest frequency derived from three different sources in the body (*N gonorrhoeae* from genito urinary tract *N meningitidis* from cerebrospinal fluid and *N catarrhalis* from nasopharynx) Consequently the source of the material from which these morphologically indistinguishable organisms are derived is usually reliable evidence for differentiation However errors in etiology have been made because absolute differentiation has not been accomplished This is particularly well illustrated by the fact that the conjunctivae and also the joints may be infected either with the gonococcus or the meningococcus and if other clinical evidence does not point to the nature of the infection complete bacteriologic identification of the organism isolated from the lesion is necessary

Pathogenesis—The portal of entry of gonococcal infections is except in unusually rare instances the genito urinary tract both in males and females The manifestations observed in medical clinics are therefore secondary to the original local infection and are in the strict sense complications of the primary gonorrhea The transport of the organisms from the initial focus to other tissues of the body is most often accomplished by spread to structures adjacent to the inflammation or by lymph channels to inguinal and other region lymph glands However for internal medicine the metastasis of gonococci usually occurs by way of the blood stream In this connection it is an interesting fact that the transfer of the organism to remote parts of the body as

the joints, is not characterized by the stormy clinical course of bacteremia but is in most instances silent since the period between the gonorrhea and the clinical appearance of gonococcal diseases may be one of com parative good health

In pathologic material there is no typical pathognomonic histologic or cytologic pic ture by which the gonococcal nature of in flammation may be diagnosed Demonstra tion of the presence of gonococci in the lesions is necessary

Endocarditis—The clinical picture of en docarditis which follows the implantation of gonococci on the heart valves is closely simi lar to bacterial endocarditis caused by *Streptococcus viridans* or some other bac terial species In addition to the cardiac find ings characteristic of endocarditis other manifestations which are commonly encoun tered consist of fever anemia petechiae embolic phenomena (lungs spleen brain etc), nephritis arthritis and others Leuko cytosis is usually well marked Secondary anemia develops rapidly In the heart itself two features of special interest are the se lective valvular involvement and the fact that preexisting valvular disease (rheumatic endocarditis or congenital abnormality) is not a prerequisite for gonococcal valvulitis Damage to the valves existing prior to the occurrence of gonococcal endocarditis has been noted in only 15 to 20 per cent of cases The aortic valves are most frequently at tacked but the valves of the right side of the heart are also the special site of gono coccal localization, occupying the second place in point of frequency of involvement Since the pathologic lesions are destructive and ulcerative the character of the mur murs is likely to change in quality and intensity as the disease progresses Suppura tive myocarditis may occur as a result of ex tension of the infection from the valves Pneumonia may follow the implantation of infected emboli in the lungs

The development of endocarditis coinci dent with the early acute phase of an initial attack of urethritis is rare The valvular dis ease occurs at a later date, ranging from two to six weeks after the beginning of gonorrhea In many instances the relation ship between the onset of genito urinary infection and endocarditis cannot be estab lished The diagnosis of gonococcal endo carditis, when suspected, is substantially aided by determining the presence of gono cocci in the genital tract even though a history of gonorrhea has not been obtained When genito urinary discharge is absent, ex amination of prostatic material following massage or cervical smears in the female are helpful and important procedures

Gonococcal endocarditis usually runs a more malignant course than that of endo carditis due to *Streptococcus viridans* the average duration of the former being five to nine weeks The course is progressive, and spontaneous remission is a great rarity Gonococcal infection may be suspected in a case of severe endocarditis with definite signs of valvular disease of the right side of the heart However the etiology can be established only by blood culture Failure to obtain gonococci from the blood stream is not an uncommon experience The unsuc cessful attempts are accounted for by dif ficulty in cultivating gonococci particularly when the size of the inoculum as repre sented by the number of organisms in 5 to 10 cc of blood may be small An additional contributing factor may be ascribed to the right sided cardiac lesion with the capil lary bed of the lungs serving as a filter before the organisms reach the general cir culation

Recovery has been reported in a few authentic cases The mortality is approx imately 95 per cent In several of the re ported cases which have recovered the course of the disease has been prolonged and subacute rather than progressively and con tinually acute in character

Arthritis—Arthritis constitutes the most common form of gonococcal infection en countered in internal medicine In the major ity of cases it presents itself as an acute febrile illness in which inflammation of the affected joints is readily apparent Although reports vary considerably arthritis probably occurs as a complication of gonorrhea in about 3 per cent or less of the cases It develops secondary to genital gonorrhea and most frequently follows the initial infec tion from one to four weeks However the interval may be longer or indeterminate Because of the fact that urethritis in males may be mild and that cervicitis in females

may be unnoticed a history of recent gonorrhea may not be obtained Direct examinations of urethral discharge or prostatic secretions or cervical exudate are important diagnostic procedures in establishing the presence of a primary focus In cases of chronic gonococcal infection of the genitourinary tract inciting causes such as trauma and others the nature of which is not understood may cause arthritis to develop without a recent acute exacerbation of the original local infection Neither the severity of the arthritis nor its incidence is dependent upon the severity of the preceding attack of gonorrhea

The onset is usually acute and accompanied by a general reaction with malaise and fever The course of the temperature during the acute period is characterized by a moderate degree of fever which runs an intermittent course and gradually subsides as the inflammatory reaction lessens Polymorphonuclear leukocytosis develops with average counts ranging from 9000 to 15 000 white blood cells Anemia does not develop unless improvement is delayed for a considerable period of time or unless the preceding gonorrhea was debilitating

Pain is a prominent symptom which in the early stages may be widespread among many joints As the acute process progressively develops involvement of one two or several joints becomes conspicuous with swelling local increased heat and redness The pain may become unusually intense and overshadow the earlier polyarthralgia Limitation of motion and muscle spasm are characteristically present

Although the monarticular nature of gonococcal arthritis has been frequently emphasized it is usually polyarticular and its distribution is predominantly among a few of the large joints Knees and ankles are most commonly affected followed in frequency by wrists elbows shoulder and hip joints In a small number of instances the infection may be limited to one of the less commonly involved joints such as the sternoclavicular or temporomaxillary The small joints of the hands or feet may also bear the brunt of an attack or their involvement may accompany that of larger joints

Fluid accumulates within the joint capsule and periarticular swelling is also present The exudate aspirated from inflamed joints is turbid due chiefly to polymorphonuclear leukocytes The number of white blood cells usually in the tens of thousands ranges from 1000 or 2000 to over 50 000 Myers Keefer and Holmes have attached prognostic significance to the total cell count When the number of cells was greater than 40 000 chronic disability usually resulted whereas in cases in which the counts were less than 40 000 complete recovery more regularly occurred

The correct diagnosis is established by demonstrating gonococci in the fluid The organisms are not found in great abundance Careful and prolonged search of centrifuged material may be necessary In many instances no gonococci are identified Cultures may reveal gonococci when direct examination is not informative Both measures may be negative Myers Keefer and Holmes believe that organisms are most likely to be present when the synovial membrane is destroyed by the intense inflammatory reaction When organisms are not present the inflammation is confined beneath the surface of the synovial membrane The demonstration of gonococci in fluids makes a somewhat worse prognosis but does not conclusively point to permanent disability since many exceptions may be encountered

The final outcome of gonorrheal arthritis is very varied Complete and permanent recovery most frequently occurs Arthritis may assume a chronic form that endures with limitation of motion long after the acute process has subsided The chronic condition may gradually improve or it may become progressively worse and result in ankylosis and permanent disability

Acute suppurative tenosynovitis may occur without arthritis and has been observed to follow trauma or involve tendons used in the patient s occupation

The so called gonococcal heel observed occasionally in association with arthritis is dependent upon periostitis of the os calcis with the development of an osteal pur Patients with this complication complain of pain in the affected heel particularly as a result of pressure Roentgenographic examination reveals an exostosis

Cutaneous manifestations occur in association with other active neisserian infections either of the genito urinary tract and adnexa or with metastatic diseases The numerous disorders of the skin are not in themselves typical of gonococcal infection with the exception of *keratodermia blennorrhagicum* a somewhat rare disease which should only be diagnosed in association with the presence of proved gonococcal disease

Meningitis and other involvements of the central nervous system are rare but occur as metastatic infections from active genital ophthalmic or endocarditic lesions Primary gonococcal meningitis has also been described Since the gonococcus and meningococcus are morphologically identical the true nature of the disease may not be recognized in sporadic cases of meningitis unless biologic identification of the strain is made

Nephritis —Proven cases of gonococcal nephritis are not common Pyelonephritis and pyonephrosis are encountered in cases of active disease of the lower urinary tract following extension of the infection upward Clinical and laboratory signs of renal insufficiency are present Surgical treatment is often required in order to promote drainage of the infection and impede further extension Acute glomerulonephritis may occur during the course of endocarditis It also has been noted in association with other active gonococcal infections Renal insufficiency develops and may be followed by uremia

Septicemia refers to the persistent presence of gonococci in the blood stream in sufficient numbers or of such a degree of toxicity that the general reaction is marked and the clinical course stormy Septicemia associated with acute primary gonorrhea is unusually rare A septic bacteremic course with metastatic infections and embolic manifestations may occur in any of the types of gonococcal infection Gonococci are recovered from the blood stream most frequently in cases of endocarditis

Diagnosis —In the early acute stages of polyarthritis the differential diagnosis between acute rheumatic fever rheumatoid arthritis other types of infectional arthritis and gonococcal arthritis is often not possible on clinical grounds The following are practical points in the diagnosis of gonococcal infections

1 History of gonorrhea, by name or symptoms Latent gonorrhea of long duration as well as a recent attack may serve as the focus from which metastatic gonococcal infections arise

2 Examination by stained smear and by culture of inflammatory exudates from lesions (joint fluids etc), for typical gram negative gonococci usually intracellular Blood cultures should be made

3 Examination for gonococci by stained smear of material derived from the genitourinary tract, viz urethra prostate seminal vesicles and draining inguinal lymph nodes in males and Bartholin's glands vagina cervix in females

Even at times of active disease the demonstration of gonococci may be difficult or even repeatedly unsuccessful Consequently, the diagnosis may not be completely proved and it becomes necessary to institute special therapeutic measures on the basis of the presence of characteristic clinical features and additional suggestive laboratory data

Complement fixation Test —When performed with properly prepared reagents the test is a valuable aid in diagnosis The reaction may not become positive until several weeks after the beginning of infection Consequently, if the result is negative but suspicion of gonococcal infection is strong repeated tests should be made at weekly or bi weekly intervals The fixation test may remain positive for many months This latter fact may be a source of error in diseases unrelated to gonococci which appear in patients who have had gonorrhea at some previous date In general a positive complement fixation test is more valuable than a negative one

Roentgenographic Changes —Early in acute arthritis the articular and periarticular swellings are noted but cartilage and bone appear normal Following complete recovery no abnormality persists When chronicity develops and damage to tissues of a joint has occurred evidence of destruction of cartilage is evident Subsequently if the disease progresses thinning of bones is noted due in part to disuse Finally ankylosis is noted particularly in joints the

articulating surfaces of which are normally in close approximation as hip ankle and wrist

Treatment —Compounds of the *sulfonamide series* are of great value in any type of gonococcal infections Sulfanilamide has proved its usefulness but it seems likely that other compounds such as sulfathiazole or the less toxic sulfadiazine are more effective

A second mode of treatment helpful in general in gonococcal infections is *fever therapy*

The literature has not yet revealed the outcome of a large series of cases of *gonococcal endocarditis* treated with the sulfonamide compounds although a few individual favorable reports have been made and the drugs should be employed as soon as possible Fever therapy induced either with hyperthermic apparatus or with intravenous typhoid vaccine has also been advocated in combination with chemotherapy The difficulties inherent in the treatment of any bacterial endocarditis are particularly applicable to the gonococcal type Consequently it is the least successfully treated of the gonococcal infections Either or both of the measures mentioned warrant trial in this highly fatal disease

Gonococcal arthritis responds well to chemotherapy In early acute cases 80 per cent recovery or marked improvement has been reported from some clinics Using sulfanilamide Bauer and associates and Culp and Cobey point to the particular success when treatment is instituted before damage to the joints has occurred The same authors also recommend that the level of sulfanilamide in the blood should be maintained at 8 to 10 mg per cent or higher The size and spacing of doses of the drug have varied in different clinics Total daily doses of 4 to 8 Gm divided into 1 to 2 Gm per dose given at intervals of three to six hours constitute the range of treatment most commonly advocated for adults of average size

Although the reports mentioned deal with sulfanilamide for treatment sulfathiazole and sulfadiazine have been found to be more potent against gonococci Consequently either of the latter compounds preferably sulfadiazine appears to be the drug of choice at the present time The course of treatment is essentially the same irrespective of the sulfonamide compound selected for use Recent reports indicate that certain gonococcal infections which do not respond to sulfonamide therapy are quickly controlled by the intravenous administration of Penicillin Within recent years fever therapy has found a valuable place in the treatment of gonococcal arthritis In obstinate cases that do not respond to sulfanilamide hyperthermic treatment offers an additional advantageous method Repeated application of dry heat to the affected joints is a helpful adjunct Splinting of the affected joint is often of great assistance in alleviating pain The splints should be applied with the joints extended in the approved orthopedic position Eradication of the primary genitourinary infection is desirable either by the use of sulfonamide drugs or by topical applications and irrigations However massage and instrumentation should be used with conservatism since local irritation may cause the metastatic disease to flare up

MENINGOCOCCAL INFECTIONS

CEREBROSPINAL FEVER

(*Spotted Fever Epidemic Cerebrospinal Meningitis Meningococcus Meningitis*)

Definition—Cerebrospinal fever is an infection with the *Diplococcus intracellularis* which occurs sporadically or in epidemics It is characterized by primary local involvement of the nasopharynx or tonsils, secondary invasion of the general blood stream, and metastatic inflammation of the meninges and more rarely of other parts of the body

History—To Vieusseux of Geneva, and to Danielson and Mann of Manchester Massachusetts belongs the credit of the earliest and independent descriptions of this disease in 1805 and 1806 In 1811 North of New York published the first monograph on the subject To Jochmann in Germany and Flexner in the United States belongs the credit of establishing serum therapy

Incidence—Sporadic cases are almost always present in any large community At irregular and infrequent intervals epidemics occur These most often arise where individuals are crowded together in new or unsanitary surroundings as in army camps jails and other institutions Nevertheless as in New York in 1905 epidemics may arise without peculiar circumstances

Etiology—The *meningococcus* was identified as the cause of meningococcus meningitis by Weichselbaum in 1887 It is a gram negative diplococcus almost strictly parasitic for man and can be grown on artificial media only if animal protein is present Toxins appear to be both intracellular and extracellular, and phagocytosis is a dominant factor in immunity Several varieties or types of the organism are described In England and the United States these number four Types I II and III are more or less well defined immunologically Type IV or 'X' comprises all organisms outside the other groups It is important to recognize that serum which is active against one type may be inert against another Apparently the disease is almost solely transmitted by 'droplet' infection from the mouth or nose of the carrier Carriers are always present in a community and may be individuals suffering from the disease or in the incubation period or chronic or casual carriers

Morbid Anatomy—During meningitis there is intense congestion, often with punctate hemorrhage in the dura In its earliest stages the disease is revealed by congestion of the pia arachnoid and choroid plexus with localized infiltrations of round and polymorphonuclear cells and erythrocytes The exudate typical of the later period of the meningitis lies between the arachnoid and the pia mater, is composed of leukocytes fibrin meningococci and red blood cells and may be thin and milky or lie in thick greenish yellow masses about the base or distributed along the sulci of the cortex and throughout the ventricles In prolonged cases with internal *hydrocephalus* or block the site of obstruction may be evident in the region of the roof of the fourth ventricle the aqueduct the foramina of Monro or in the spinal subarachnoid space The brain is compressed and flattened and the ventricles distended In some acute cases the brain stem may be forcibly wedged in the *foramen magnum*

Insufficient attention has been paid to the *encephalitis* accompanying the infection Perivascular foci made up of round cells pus cells red blood corpuscles and meningococci may be found throughout the encephalon Macroscopic areas of hemorrhagic or purulent character may also be found Changes in the spinal cord and its coverings similar to those found in the cranium may be seen Intracranial hemorrhage is not infrequent

Pericarditis endocarditis arthritis pneumonia pleurisy empyema panophthalmitis empyema of the accessory nasal sinuses epididymitis peritonitis and adrenal hemorrhage all may occur and indicate the widespread invasion of the host by the *meningococci* Petechial hemorrhages may be seen on all serous surfaces

Symptoms—The infection may be divided into 3 stages the first a local infection of the upper air passages the second a general invasion of the blood stream or stage of *meningococcus* sepsis the third a stage of metastatic localization usually in the meninges not infrequently in joints pericardium endocardium lungs skin and other regions These 3 stages may merge and coexist

The *first* or *carrier stage* may exhibit no symptoms other than the local presence of

meningococci or there may be tonsillitis pharyngitis sinusitis or conjunctivitis with moderate purulent discharge containing the characteristic diplococci

The *second stage* is one during which the organisms are dispersed by the blood stream from the initial focus in the upper air passages Under appropriate conditions as in military organization or closely observed epidemics this stage can be readily recognized by the following features the patient is dull apathetic indifferent he plaintively resents disturbance responds in monosyllables with the expenditure of a minimum amount of energy and prefers to lie on the side with knees drawn up and head bent forward There is no modulation of voice or play of expression Silence and immobility are striven for and active delirium or coma is infrequent This striking deviation from the normal mentality at once arrests the attention of the experienced observed The oral secretions are dry and viscid and moderate cyanosis or ashen pallor is common In 300 cases the initial temperature averaged 101° F Slight chills are frequent The pulse is rapid There is complaint of being sore all over and arthralgia or a mild polyarthritis often occurs The deep reflexes are exaggerated and may be unequal There is hyperesthesia

The most distinctive feature is the *rash* which consists typically of a capillary hemorrhage into the skin and mucous membranes In size the spots vary from a pinpoint to irregular areas 0.5 inch in diameter They are dusky red do not vanish on pressure and fade within three or four days leaving a rusty stain *Purpura* is a feature of the fulminating cases Milder prolonged types exhibit a maculopapular rash resembling the roseola of enteric fever except that the individual spots are larger Bleb formation often followed by local gangrene has been described *Gangrene* of the toes or of an entire extremity is rarely seen The leukocyte count is constantly increased numbering from 15 000 to 60 000 with an average polymorphonuclear percentage of 90

In this stage meningeal symptoms and signs are absent The *spinal fluid* is clear and has a normal cell count it may or may not contain an increased quantity of globulin and an occasional extracellular diplococcus The nasopharynx the skin lesions or the blood stream may reveal *meningo*

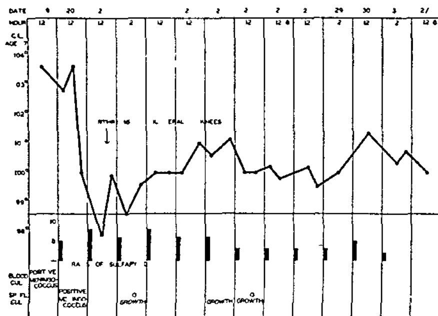

Fig 19 —Temperature chart of a forty-seven year-old chauffeur (C L) who came into the hospital in the premeningitic stage The following morning developed rash stiff neck, stupor Treated with 58.5 Gm of sulfapyridin over a period of thirteen days Improvement very rapid in the next three or four days Temperature curve affected by meningococcus arthritis of both knees which developed on the third day

cocci provided appropriate methods of cultivation are used This stage of sepsis may last a few hours or many days or weeks Rarely the third, or metastatic stage does not occur at all

The *third* or *metastatic, stage* is ushered in by a bursting headache, vomiting, chilly feelings and fever, frequently, in children with delirium and convulsions The patients exhibit retraction of the head stiffness of the neck, positive Kernig s and Brudzinski s signs, a relatively slow pulse, often with vagus irregularities and the *tache cerebrale* As the course of the temperature is erratic no typical chart can be drawn There may be quotidian or tertian rises, with intervening remissions or intermissions Afebrile periods lasting for hours or days may be followed by renewals of fever, often with chills Prolongation of fever beyond the seventh day suggests that treatment is inefficient that some complication has arisen or that serum sickness has developed With increased intracranial pressure the veins of the forehead may become distended and the respiration be of the Cheyne Stokes Biot or undulatory type Insomnia, delirium and coma may occur

In the early stages the pupils are dilated later, irregularities appear and a varying *strabismus* from irritation or paralysis of the oculomotor nerves is frequent Other rarer findings are fulness of the retinal veins retinal edema, hemorrhages or with internal hydrocephalus papilledema Blindness of central origin may occur but is rarely permanent Herpes of the lips or face is one of the commonest signs It is rarely seen before the fifth day and seldom leaves scars In infants bulging of the fontanels is an important sign The leukocytosis of the early stages continues Meningococci have been demonstrated in the leukocytes of the ordinary stained blood film Positive blood cultures can be obtained in from 5 to 80 per cent of cases but are most often found in the premeningitic stage when special technic is employed Except for the initial vomiting the gastro intestinal tract is not involved An epididymitis of benign course and outcome may occur in some epidemics Retention of urine may be overlooked Bronchitis and broncho or lobar pneumonia may occur at the onset or as a complication

In the *fulminating type* there is an overwhelming general toxemia with predominant hemorrhagic skin lesions The temperature may be subnormal or unusually elevated. Death may occur a few hours after onset. Petechial spots of all sizes and diffuse purpura are typical Differentiation from the hemorrhagic types of the exanthemata may be possible only on epidemiologic or bacteriologic grounds Meningitis may not occur The blood culture is practically always positive

Atypical meningococcic infections are not uncommon These may be manifested by prolonged, irregular fever, with arthritic symptoms petechial or maculopapular rashes, enlargement of the spleen a positive blood culture, and extrameningeal foci of infection Meningitis may not occur or may appear after many weeks of general symptoms

In no acute disease is the course more variable Recrudescence and relapses are present in 20 to 30 per cent of cases In rare instances there have been several attacks within two years Among the *complications* are purulent conjunctivitis panophthalmitis transitory amaurosis rarely optic neuritis and retinitis Otitis media is common Deafness following involvement of the eighth nerve is usually permanent Pericarditis and vegetative endocarditis occur The blood pressure is low in the stage of sepsis, but with increased intracranial pressure in the later meningitis or block it becomes elevated An acute arthralgia or polyarthritis is often an initial symptom and an erroneous diagnosis of *purpura rheumatica* may be made As a late complication a purulent monarthritis usually of the knee may occur The prognosis in such cases is usually good A third type of arthritis is the effect of serum therapy and may occur seven or more days after beginning the treatment

Internal Hydrocephalus or Subarachnoid Block.—Most common in infants this most serious complication arises from organization of exudate in the system of channels through which the cerebrospinal fluid circulates The subarachnoid block may occur at the roof of the fourth ventricle at the sites of the foramina of Luschka and Magendie in the aqueduct of Sylvius the foramina of Munro or even in the spinal subarachnoid

space The symptoms may be acute with unbearable headache cyanosis of the face and fulness of the veins of the forehead and retina delirium and not infrequently, sudden death—at times following lumbar puncture or chronic with weeks of rapid emaciation clouded mentality enhanced meningeal irritability, ocular palsies and eventual death Unless relieved by drainage hydrocephalic meningitis is always fatal

In the early stage of infection when there are symptoms of generalized disease the *cerebrospinal fluid* may be altogether normal and may remain so for hours days or in rare cases weeks or throughout As secondary meningitis develops isolated organisms may be found later globulin an increase in the number of mononuclear and then polymorphonuclear cells When the cell count is more than 400 per cubic millimeter the fluid becomes cloudy, later it may be *made very thick with pus cells fibrin and* meningococci The latter are found largely within the pus cells and are comparatively infrequent in most cases In general the presence of a large number of organisms suggests ome other form of meningitis Occasionally the spinal fluid is very thick and coagulates on standing Blood may be present as the result of the needle puncture or of rupture of the ependymal veins Dry taps may result from block from clogging of the needle by too thick exudate from faulty technic or without apparent cause As the infection subsides the cerebrospinal fluid becomes clear contains less protein fewer cells a large proportion of lymphocytes and fewer organisms or none at all In some of the prolonged cases the fluid may become clear but is under increased pressure contains a slightly increased number of cells and usually no organisms—the picture suggesting a hypersecretion Shortly after the onset of meningitis *meningococci* can be recovered from the cerebrospinal fluid by culture with little difficulty After serum treatment is under way it is very difficult to obtain a positive culture A safe clinical rule is to proceed at once with antimeningococcic serum or chemotherapy whenever a febrile condition is accompanied by a cloudy cerebrospinal fluid even when organisms cannot be found In infants irritability drowsiness stupor or coma vomiting convulsions muscular rigidity, increased tendon reflexes bulging fontanel and hemorrhagic rash and irregular respiration invite attention to the possibility of this disease

Diagnosis —Although sporadic cases are common the presence of an epidemic is an important factor Meningitis may exist concurrently with other infections The premeningitic stage may be recognized by the slight fever the peculiar manner attitude and facies the cutaneous vasomotor disturbance or the typical rashes the marked leukocytosis with polymorphonuclear increase the heightened and ill balanced activity of the reflexes the presence of infection in the upper respiratory tract the general aching and soreness or arthralgia and by the demonstration of meningococci in the nasopharynx by blood culture or in the thoroughly centrifuged cerebrospinal fluid With the onset of definite meningeal symptoms *diagnosis is rarely difficult and the evidence* obtained by lumbar puncture is almost always decisive

Meningismus —In the *acute infections* particularly in childhood symptoms of meningeal irritation may be very prominent and confusing Scarlet fever influenza typhus fever pneumonia mumps gastro enteritis and tonsillitis may be attended by headache vomiting stiffness of the neck and positive Kernig s signs During these diseases however the cerebrospinal fluid is clear and rarely contains an increased number of leukocytes Fifty or more cells per cubic millimeter may be present but the fluid does not become purulent and the development of the original disease makes the picture clear In the differentiation of influenza and typhoid fever from meningococcic infection the lack of leukocytic increase in the blood in both these diseases is decisive While the maculopapular eruption so common in typhoid fever is occasionally seen in meningococcic infections the longer incubation period the longer more regular course with abdominal symptoms the more uniform picture and the positive bacteriologic or serologic evidence of typhoid provide means of differentiation

Sepsis with meningeal or cerebral metastasis may give a confusing picture The portal of entry the frequent involvement of the endocardium the bacteriologic evi

dence obtained from blood culture and from direct examination of the spinal fluid usually serve for differentiation The petechiae accompanying the common types of streptococcic sepsis are much smaller than the hemorrhagic spots seen in meningococcus infection The cerebral form of poliomyelitis *in contrast with meningococcic meningitis* often begins with symptoms of a gastroenteritis The temperature is higher at the onset and declines more promptly while herpes and hemorrhagic eruptions are absent and the evidence of meningeal irritation is usually less The spinal fluid shows a higher proportion of lymphocytes and the bacteriologic evidence is, by ordinary methods negative The reflexes are usually diminished and paralysis is common *Tetanus* may be differentiated by the paroxysmal character of the attacks—the trismus, the history of a wound the absence of headache and the lack of pus cells in the cerebrospinal fluid In *tuberculous meningitis* the history of similar infection in the family, the slower onset the evidence of tuberculosis elsewhere in the body the absence of hemorrhagic rashes and of marked leukocytosis rarely the finding of choroidal tubercles the lesser increase in the number of cells in the spinal fluid and the presence of tubercle bacilli usually serve to clear up the problem

Septic meningitis caused by the common pyogenic organisms is usually secondary to a focus in the middle ear the accessory nasal sinuses scalp or face Organisms are usually abundant in the cerebrospinal fluid which becomes rapidly thickened by pus and the course is usually very short and fatal Other conditions which are rarely confused with meningococcus meningitis are *delirium tremens rheumatic fever* with cerebral involvement *subarachnoid hemorrhage diabetic coma uremia tetany* and *cerebral abscess hemorrhage* or *thrombosis*

Prognosis is extremely difficult and one can never safely predict what is going to happen in a given case of meningococcus infection The general mortality rate before the introduction of sulfonamide therapy was very high averaging about 50 per cent for the country at large This unfortunately was true in spite of the fairly widespread use of antimeningococcus serums However in a number of selected hospital series of cases properly treated with type specific serum, the case fatality rates were as low as those recently obtained with sulfonamide drugs The mortality in cases properly treated with sulfanilamide* and particularly with its later derivatives sulfapyridine sulfathiazole and sulfadiazine should not exceed 5 to 10 per cent The lowest mortality rate is obtained when treatment is begun on the first day of the disease and the rates rise according to the time which has elapsed between the onset of the disease and the time treatment is begun In the acute fulminating cases with extensive purpuric eruption and adrenal and other visceral hemorrhage (Waterhouse Friderichsen syndrome) death usually occurs within twelve to forty eight hours of the first symptom, and in spite of intensive treatment Age is still an important factor the highest mortality rates occurring less than the age of three and in those more than fifty years old Failure to respond promptly to treatment is ominous and this is equally true of serum and of sulfonamide therapy Patients with hydrocephalus or endocarditis seldom recover, although death may be delayed in cases treated with sulfonamide Early arthritis usually responds rapidly to chemotherapy The occurrence of cranial nerve involvement is serious With general recovery however involvement of most of the cranial nerves usually clears but deafness and blindness usually remain permanent and complete The mortality in early phases of an epidemic has generally been higher than toward the end but this may not be true when chemotherapy is widely used The prognosis in meningococcemia in the absence of meningitis is very favorable The acute cases respond rapidly to either specific antiserum or sulfonamides The outcome in chronic meningococcemia is likewise favorable until the late complications namely meningitis or endocarditis supervene Without any specific therapy the mortality in such cases averaged about 25 per cent Chemotherapy or serum therapy should materially reduce this figure

Treatment —The chief reliance at present is on adequate chemotherapy with sulfonamide drugs which are highly effective both in meningitis and in the meningococcemias in the absence of meningitis

Antimeningococcus serum may be useful as an adjunct While the antiserum may sometimes be employed early in the disease in very severe and rapidly progressing cases its use is usually reserved only for those cases in which proper sulfonamide therapy fails to control the active infection

Chemotherapy—All of the sulfonamide drugs that have come into common use namely, sulfanilamide sulfapyridine sulfathiazole and sulfadiazine are highly effective in the treatment of all types of meningococcal infections Failures from chemotherapy may be expected however when endocarditis is already well established or where attempts are made to clear up the carrier state Sulfadiazine is the drug of choice because (1) it gives the least toxic effects (2) it penetrates well into the cerebrospinal fluid and (3) it is at least as effective as the other compounds There may be situations where it is impossible to supply a sufficient fluid intake in order to insure an adequate output of urine as for example in military units under tropical field conditions Sulfanilamide should then be used because of its greater solubility and the dangers of renal complications will thus be minimized When first introduced sulfathiazole was thought to be contraindicated in the treatment of meningitis because it penetrates poorly into the cerebrospinal fluid where this compound reaches concentrations which are usually about one-third of those found in the blood at the same time Sulfanilamide sulfapyridine and sulfadiazine on the other hand are usually found in the spinal fluid in about 60 to 90 per cent of the corresponding blood concentration In actual practice however sulfathiazole has proved at least as effective as sulfanilamide or sulfapyridine either because of its greater antimeningococcus action or because the concentration of the drugs in the cerebrospinal fluid is not of great importance

Dosage—In general doses of 6 to 9 Gm per day are recommended for adults and 0 03 to 0 1 Gm per kilogram of body weight per day for infants and children the larger doses being reserved for those less than two years of age The dose is the same for each of the four compounds mentioned The initial dose should be equal to a full daily dose and subsequently the daily amounts are given in four or six equal parts evenly spaced throughout the twenty four hours In the case of sulfanilamide or sulfathiazole the four hourly schedule is necessary

Parenteral Administration.—In severe cases in comatose patients or when treatment is begun late in the course of the disease it is advisable to give an initial dose parenterally Sulfanilamide may be given as 0 8 per cent solution in physiologic saline either intravenously or preferably, subcutaneously The other compounds because of their very low solubility must be used in the form of their sodium salts These are administered either as *5 per cent solutions* in distilled water intravenously or as 0.5 to 1 per cent solutions in physiologic saline either intravenously or subcutaneously Intravenous sulfonamides should never be given together with blood transfusions or even in the same apparatus Intrathecal injections have been used either in the form of 0 8 per cent solution of sulfanilamide or as 0.5 to 1 per cent solutions of the sodium salts of the other derivatives in physiologic saline (not in distilled water) While such injections are well tolerated if these concentrations are not exceeded and no untoward effects have been noted from them this procedure is probably unnecessary and is not recommended

Oral treatment should be started as soon as possible but if the patient remains comatose it may be necessary to continue with parenteral therapy for one to three days or even longer In that event the daily dose is divided into three parts and given at eight hour intervals It is desirable, especially in severe cases to maintain blood concentrations of about 10 mg per 100 cc or slightly higher when sulfanilamide or sulfapyridine is used above 5 mg per 100 cc in the case of sulfathiazole and about 15 mg per 100 cc of sulfadiazine

Except when sulfanilamide is used it is important to insure a good urinary output (about 1200 cc daily in adults) throughout the course of treatment and to supply fluids parenterally in the form of physiologic saline or 5 per cent glucose in distilled water if necessary In all sulfonamide treated cases it is also desirable to keep the urine alkaline either by giving sodium bicarbonate orally

with the drugs or by administering sixth-molar sodium lactate solution parenterally if necessary

Sulfonamide therapy should be maintained on full doses until from three to five *days after all evidence indicates that the* infection has subsided that is, after the temperature has stayed normal, the symptoms have cleared, the cerebrospinal fluid has remained sterile and its cellular, sugar, and protein contents have returned to or near the normal values

Antimeningococcus serum was formerly used in every patient in whom meningitis was suspected, and it was administered both intravenously and intrathecally Since the value of sulfonamide drugs has become established very few physicians continue to use antiserum at all except intravenously or intramuscularly in the severest cases The dosage varies, of course with the potency of the preparations and unfortunately, the methods of standardization are not very satisfactory It is also important to ascertain that the serum contains the specific antibodies for the infecting type of meningococcus All the usual precautions for serum injections must be observed The initial injection is usually about 100 cc of unconcentrated preparations or corresponding amounts of concentrated This amount may be repeated at twelve hour intervals if necessary The intrathecal injection of antiserums has been considered responsible for many instances of block in the spinal canal and, since there is no definite evidence that it has any value it is no longer used 'Antitoxic' serum has been recommended by Hoyne in preference to antibacterial serum but it is doubtful whether the former had any therapeutic virtues not found in the latter

Lumbar puncture should be performed for diagnosis before treatment is begun Thereafter the procedure is repeated for relief of the symptoms and signs of increased intracranial pressure for the purpose of obtaining evidence concerning the progress of the infection Care must be taken to allow the fluid to escape slowly drop by drop in order to avoid sudden lowering of the pressure With the use of sulfonamide therapy there is no longer any reason to withhold this procedure from patients suspected of having meningococcemia if there is any sign or symptom of meningitis It is no longer considered good practice to give any medications by the intrathecal route in meningococcal meningitis, and this is true of sulfonamides and of antiserum

The Stage of Sepsis (Meningococcemia without Meningitis) —In this stage the disease readily responds to sulfonamide therapy given in full doses Sulfadiazine at present is the drug of choice

Treatment of Symptomless Carriers—The precise value of antiseptics or vaccines used to eradicate meningococci from the upper air passages is not known It must be recognized that in two thirds of the cases these organisms disappear spontaneously In general it seems better to trust to nature than to impair the integrity of the mucous membranes by strong antiseptics If there is obvious disease of the tonsils, paranasal sinuses, or pharynx this may be eradicated by surgical means, and such measures are often followed by disappearance of meningococci When operations on the upper respiratory tract are undertaken on meningococcus carriers, it is probably wise to administer some sulfonamide for twelve hours prior to the operation and to continue its use for twenty four to forty eight hours later in order to insure against a spread of infection

Cause of Continued Symptoms —Seven days after the beginning of serum treatment *serum sickness* may cause moderate or even high temperature erythema urticaria swelling of the lymph glands enlargement of the spleen or arthritis *Panophthalmitis* may be accompanied by an elevation of temperature so also may *otitis media pericarditis endocarditis meningococcic arthritis hydrocephalus* or other late complications Occasionally *abscess of the cerebrum* may pursue a prolonged febrile and fatal course Serum sickness demands no special treatment Subcutaneous injections of 5 to 10 minims of adrenalin may give transitory relief An eye destroyed by purulent invasion should be enucleated after several weeks have elapsed in order to give a chance for thorough walling off of the focus Pericarditis with effusion should be treated by aspiration and continued chemotherapy Endocarditis is usually evidenced by posi

tive blood culture and is likely to be fatal but active treatment should be tried persistently Arthritis should be treated by rest and if much effusion is present by aspiration Hydrocephalic meningitis or block demands energetic and prompt measures Drainage must be effected within a few days if death is to be prevented Drainage can often be secured by puncture of the *cisterna magna* This should always be resorted to if lumbar puncture does not give a free flow of fluid Puncture of the lateral ventricles is a simple procedure in children and should be carried out without hesitation when there is evidence of obstruction in the subarachnoid space In adults if drainage by the lumbar or cistern route is unsuccessful ventricular drainage can be accomplished by trephining the skull Sometimes a combination of lumbar and cistern puncture or of cistern and ventricular puncture with through and through irrigation with salt solution is effective in securing drainage In the acute swelling of the encephalon in the early stages of the disease which is often shown by bursting headache cyanosis full veins of the forehead and marked delirium the attempt to reduce the volume of the cranial contents by the administration of hypertonic solution of glucose (usually 100 to 200 cc of a 50 per cent solution) intravenously or by the giving of sulfate of magnesium by mouth or rectum is advisable Venesection may also be of use in selected cases Involvement of all the cranial nerves except the eighth usually clears up spontaneously with time Deafness caused by involvement of the eighth nerve in this disease is usually permanent It is possible *though unlikely that relapses may be* guarded against by the use of vaccines during convalescence The administration of three or four doses of 500 000 000 killed meningococci at weekly intervals may be advised

MENINGOCOCCAL SEPSIS

Not infrequently the meningococcus in its invasion of the blood stream leaves the meninges unscathed Cases of this kind may be acute and not different in clinical aspects from the stage of sepsis already described in the previous section on cerebrospinal fever

However there is a group of subacute or chronic cases of meningococcemia with features meriting separate description In such the picture is that of a prolonged general infection Fever always present is of a very irregular remittent type with quotidian tertian or less frequent peaks often marked by chills The spleen is enlarged and firm The most striking and often diagnostic manifestations are on the skin In addition to the hemorrhagic rashes already described under spotted fever there may be a maculopapular roseola at times mistaken for rose *spots or erroneously called* erythema nodosum or purpura rheumatica These are seen about the joints on the extremities or the torso are generally sparse and appear in successive groups A subacute arthritis may be the chief evidence of meningococcic sepsis Most often the larger joints are involved perhaps successively in a relatively mild type of inflammation with exudate in but not around the joint space

The two most erious results of such a meningococcic sepsis are meningitis and endocarditis Meningitis may occur many months after the onset of the general infection *Endocarditis generally of the mitral*

or aortic valves, runs an acute or subacute course almost always fatal Pericarditis pleurisy, pneumonitis peritonitis and epididymitis are other rarer complications The blood culture is positive A polymorphonuclear leukocytosis is constant

The duration of meningococci infections of this type is most variable They usually last several weeks and certain cases have been prolonged for a year A duration of six months is not rare

The prognosis is by no means discouraging Spontaneous recovery often takes place after months of fever Cases with meningitis have the prognosis of cerebrospinal fever those with endocarditis are almost if not quite hopeless Arthritis clears without residual disability

In the diagnosis one must consider chiefly sepsis of other origin subacute bacterial endocarditis infectious arthritis, rheumatic fever, the purpuras enteric fever the various forms of typhus and erythema nodosum

The treatment consists in the use of the sulfonamides as advised under Chemotherapy in the preceding chapter If necessary this may be supplemented by the intravenous administration of antimeningococcal serum in large amounts—100 cc for an adult—daily for three to five days or until symptoms are controlled It is important to obtain serum from different sources if results are not satisfactory Vaccines may be tried but are experimental Such general measures as transfusion if there is anemia adequate nourishment and supportive measures in general are not to be neglected (See Chemotherapy)

BACILLARY INFECTIONS

DIPHTHERIA

Definition—Diphtheria is an acute infectious and contagious disease caused by the *Corynebacterium diphtheriae* or *diphtheria bacillus* It is characterized by the formation of a fibrinous exudate on the mucous membranes of the respiratory tract and by constitutional symptoms due to the absorption of toxins from the local lesion

History—Aretaeus and Galen described ulcerative membranous lesions and Aetius was acquainted with palatal paralysis a frequent sequel to diphtheria Epidemics occurred in the Middle Ages and were described by various English French and Spanish writers Bretonneau gave excellent descriptions of the disease in connection with violent outbreaks in Tours He grouped the diseases known as putrid sore throat, "cynanche maligna and angina suffocativa under the term diphtérite Trousseau who confirmed Bretonneau s observations subsequently changed the name to diphtérie The discovery of the diphtheria bacillus by Klebs in 1883 and its isolation and cultivation one year later by Löffler established the definite bacteriologic entity of the disease In 1888 Roux and Yersin demonstrated the soluble toxin of the disease by passage through a porcelain filter The subsequent fundamental researches of von Behring and Ehrlich dealt with the character of the toxin and the determination of its strength and in 1891 von Behring and Wernicke announced the discovery of antitoxin

Further progress in the control of diphtheria was made when the Health Department of New York City in 1893 adopted under the direction of Park the use of cultures for control of the period of isolation and for diagnosis and when Schick in 1913 described the intradermal toxin reaction for the determination of individual immunity In 1913 von Behring utilized, for the first time injections of toxin antitoxin mixtures in children for active immunization against diphtheria In 1917 Park inaugurated widespread immunization with toxin antitoxin a procedure which has reduced the morbidity and mortality of diphtheria to extremely low levels In 1924 Ramon reported his researches on formalized toxin or anatoxin which later largely replaced toxin antitoxin mixtures for immunization Intubation for relief of obstruction of the larynx was devised by O Dwyer of New York, in 1885 although attempts had been made previously by Bouchut Tracheotomy was especially developed and popularized in the early nineteenth century by Bretonneau and Trousseau whose tube is the standard today

Incidence—Diphtheria occurs chiefly in the temperate zone and is rare in the tropics It is endemic in the larger cities and shows a marked increase in the fall and winter months Outbreaks of great virulence occur at times but since the introduction of active immunization these have tended to disappear

Etiology—Diphtheria is caused by the diphtheria bacillus which is found on the surface of the affected mucous membranes and has very slight capacity to invade the body The symptoms and damages of the disease are due to the toxin which is absorbed from the surface of the infected areas

Contributory causes include *local trauma* as incision or operation on the throat and respiratory infections such as colds measles etc Diseased tonsils favor the malady and tonsillectomized persons are less frequently and less severely affected

Immunity is dependent on the presence in the blood of specific antitoxin which results from recognized attacks of the disease

and is frequently present with advancing age without known attacks having occurred. This "natural" immunity probably results from mild or unrecognized attacks and subclinical infections. At birth immunity is present in about 80 per cent of cases, being derived from the mother through the placenta. This immunity rapidly drops during the first year and at the beginning of the second year only 20 per cent still retain it. It rises definitely from this point to reach about 50 per cent by the tenth year. There is a slower rise through the succeeding age periods, finally reaching about 80 per cent in late life. Immunity is higher for the same age periods in urban than in rural populations, and in crowded sections of cities than among the well-to-do.

Antitoxic immunity as shown by a negative Schick test was believed at first to indicate $\frac{1}{30}$ antitoxic unit per cubic centimeter of blood serum, but numerous subsequent studies have shown that about $\frac{1}{250}$ unit per cubic centimeter more nearly represents the immunity level. There are, however, other factors which influence immunity. In spontaneous recovery antitoxin may not be demonstrable for days or weeks. The influence of wounds in the mouth, throat and skin shows clearly that there is some degree of protection from an intact surface, and it is not improbable that there is also some bactericidal and, possibly, cellular immunity. Immunity after an attack may be short, at least in antitoxin treated cases, and a considerable number lose their immunity in the course of years.

The incidence is highest in children from one to five years of age. In the United States, 64 per cent of all cases occur in children below five years, and over 80 per cent below ten years of age. Since prophylactic immunization was instituted there has been evidence of a rising age incidence, as occurred in smallpox after the introduction of vaccinia. Race influences immunity, and in New York and Boston Schick tests have shown a lower "natural" immunity in Italian children than in other races. Diphtheria is a disease of man; diphtheritic diseases in animals are not due to the same cause. The disease is spread by direct contact or droplets chiefly, and by indirect contact with infected objects such as handkerchiefs, towels, cups, pencils, and toys. The bacillus may remain viable for many weeks if deposited in sputum or membrane. Outbreaks from infected milk were not infrequent before pasteurization. The contamination of the milk occurs directly from human sources or at times, indirectly through infection of the teats.

Bacteriology.—The diphtheria bacillus is a slender rod-shaped organism which in cultures shows marked variation in size, shape and staining. As a rule the bacilli are arranged in parallel or V-shaped formation. They are straight or slightly curved and when stained show granular, barred or solid protoplasm, usually with dark granules at the poles. The granular forms with dark-staining polar bodies are characteristic. The bacillus is gram-positive and can be readily recognized by Löffler's methylene blue stain or by differential stains, such as Albert's, Hunt's or Neisser's. Smears directly from the lesions may show characteristic bacilli in about 80 per cent of the cases but present greater difficulties in recognition than cultures. The bacillus grows well in Löffler's medium of glucose bouillon and blood serum at pH of 7.6.

The organism is readily killed by heat, by tricresol or formalin, and by direct exposure to the sun's rays. It may survive outside the body in pieces of membrane for seventeen weeks.

The diphtheria bacillus produces a *soluble toxin* which is destroyed by heating to 75 C. for ten minutes or to 100 C. for one minute. This toxin when injected into guinea pigs, even in doses as small as 0.02 c.c., causes death in the same manner as when the bacilli have been injected.

Diphtheria-like bacilli comprise a large group, most of which are harmless. Some of these differ sufficiently in size, shape and staining reaction or in cultural characteristics to be separated from the diphtheria bacillus. Others, however, can be distinguished only by virulence tests. The cutaneous test is now more generally used than the lethal test which, however, is somewhat more accurate. *Bacillus xerosis*, which has been found in certain cases of conjunctivitis and on normal and diseased mucous membranes, resembles the barred form of diphtheria bacillus. *Bacillus hofmannii*, the far-

thest removed from the diphtheria bacillus, is a short straight oval bacillus with rounded ends and one lightly stained transverse septum It is nonvirulent

Morbid Anatomy—The lesions of diphtheria are both local and general The former are due to the action of the toxin locally on the tissues at the site of the infection, the latter to the toxin absorbed through the lymph and blood channels

In a series of 251 fatal cases reported by Mallory at the Boston City Hospital a definite membrane which varied in extent and location was observed in 148 patients with the following distribution

Location	No of cases
Larynx	86
Tonsils	74
Trachea	73
Epiglottis	67
Bronchi	44
Nares	43
Soft palate including uvula	15
Esophagus	12
Tongue	9
Stomach	5
Duodenum	1
Vagina	2
Skin of ear	1
Conjunctiva	1

In the living patient the membrane is most frequently seen on the tonsils palate and pharynx

Local Lesions—The local lesions are in all situations essentially of the same character namely, degenerative changes in the epithelial cells and an abundant fibrinous exudation from the blood vessels to the surface and into the underlying tissues As a result there is formed on the epithelial surfaces a membrane which is so striking and characteristic a feature that the disease has been named from it Sometimes when the epithelial cells are necrotic and the destructive process involves the underlying tissue the membrane formation extends into the submucosa The diphtheria bacilli are present on the surface and the superficial parts of the false membrane but in the deeper layers of the false membrane itself they are few or absent

Macroscopically the membrane varies in appearance and consistency The color is usually gray but it may be yellowish green or at times reddish black because of extravasated blood it may be white especially after subsidence begins Usually the membrane retains its form and may be removed or discharged as a more or less complete cast of the structure on which it is formed

Systemic Lesions—The systemic lesions involve chiefly the heart, the kidneys and the nerve fibers The heart muscle undergoes fatty degeneration in more than half of the fatal cases This is always more marked in the vicinity of the endocardium There is also interstitial myocarditis which may lead to extensive formation of fibrous tissue The kidneys show acute degeneration of the epithelium, which leads to cloudy swelling of the cortex Interstitial changes are also fairly common In the more severe cases the kidneys are greatly enlarged The spleen is swollen and congested and the malpighian bodies are prominent Bronchopneumonia is frequently present in infants and young children and is a complication in nearly all the fatal cases of the laryngeal form As a rule it is due to other micro organisms such as the streptococcus or pneumococcus Degenerative changes occur in the peripheral nerves The medullary sheath undergoes fatty degeneration and is broken up into globules The axis cylinder is also involved Both the sensory and motor fibers may be affected but the latter strikingly so There may be degeneration of the columns of the posterior cord Degeneration of the anterior horn cells has also been described

Symptoms—The usual period of incubation is from two to five days The initial symptoms are usually slight and vary greatly with the location of the disease slight fever 99° to 102° F lassitude malaise and sore throat may occur Sometimes the patient does not remain in bed and occasionally marked diphtheria may be found in active children without any complaint The local lesions begin most frequently in the pharynx especially affecting the tonsils the larynx the nose or the nasopharyngeal mucous membrane

Pharyngeal Diphtheria—In the early stages of pharyngeal diphtheria congestion of the fauces and tonsils is followed by the appearance of a thin grayish film which gradually or rapidly thickens until the dense pseudomembrane is present It may be unilateral or bilateral and extend over a part of the uvula palate or postpharyngeal wall

The membrane is raised usually evenly contoured and well defined It is not easily removed until clearing has begun and on forcible removal usually shows small bleeding points Small, spotty multiple patches of membrane are not usual in diphtheria

There may be little or no *edema* but in virulent cases swelling is present and in malignant cases it may be very marked Rarely, swelling may be conspicuous for two to four days before a membrane appears The *redness* in diphtherial inflammation is characteristically dull When intense it often has an almost cyanotic hue As the membrane develops a relatively small margin of the red area is left exposed In advanced cases the absence of redness is often a striking feature There may be *enlargement* of the *glands* or *swelling* of the tissues of the neck which in severe cases may extend from ear to ear and down to or even include the chest In *malignant* cases not treated early the picture is striking The extensive swelling and membrane often becoming dark from hemorrhage the throaty voice and stridor the fetid odor the dysphagia the serosanguineous discharge and the swollen neck are typical The mind is clear but drowsiness and a mild delirium which disappears on waking are often seen Deep stupor or delirium rarely occurs except at the very end

The temperature is usually not high 100° to 102° F though temperatures of 104° F or more are occasionally encountered The temperature may be high at the onset and drop rapidly as the disease advances The pulse varies with the severity of the infection

Hemorrhages from the nose and throat are seen in severe cases and epistaxis is not a rare symptom even in mild cases In the hemorrhagic form hemorrhages from the nose and throat or the genito urinary tract and into the skin and mucous membranes as well as the organs are a striking feature

Nasopharyngeal Diphtheria—Nasopharyngeal diphtheria is of two types the anterior and the posterior In the former the disease is mild and if no extension occurs usually not fatal It is characterized by a serosanguineous discharge which often excoriates the lip and by nasal obstruction The membrane may be seen in the anterior nares on the septum or turbinates or lining the whole nostril It may be obscured by the profuse discharge In mild cases there may be no membrane but many of these can be proved not to be diphtheria even if diphtheria bacilli are present The constitutional symptoms are slight or practically nil and the course in untreated cases is often indolent lasting days or even weeks without much change In the postnasal region on the other hand, diphtheria is frequently malignant and unless promptly treated may have a grave prognosis Swelling high up in the neck below the ears nasal obstruction thick or nasal voice and either nasal or postnasal discharge and obstruction may occur Because of the location the nature of the infection is often obscure The inflammation in a short time may spread downward on the posterior palate or pharyngeal wall into the pharynx In some cases the membrane projects downward from the adenoids like a stalactite

Laryngeal Diphtheria—Laryngeal diphtheria formerly called membranous croup is the most fatal form It occurs most commonly from six months to five years of age but no age is entirely free The onset is characterized by croupy cough followed in a few hours or days by dysphonia or aphonia stridor on both inspiration and expiration and finally dyspnea The accessory muscles of respiration come into use and the respiratory rate may be increased but usually not strikingly so As the obstruction increases the increased respiratory effort may be inadequate and cyanosis appears The patient is restless takes but small amounts of nourishment and shows distress and fatigue If these symptoms continue without relief vasomotor collapse gradually develops the breathing is less forceful cyanosis is replaced by a gray pallor and clammy skin the mental state becomes apathetic and the patient dies The rapidity with which these sequences occur varies with the size and strength of the patient and the virulence of the infection The obstruction may be due to swelling or membrane or both If due to membrane spontaneous loosening and coughing up of the membrane may yield partial or complete relief or if detached and not expelled sudden changes in the degree and character of the obstruction or even complete asphyxia may ensue Large casts of the

larynx or trachea or of the whole pulmonary tree may be brought up

When the membrane extends down the trachea or into the bronchi as frequently occurs this may not be clinically evident until it has been loosened from the tracheal or bronchial wall or until it reaches the bronchioles when dyspnea may occur, usually with increased *expiratory* stridor A valvelike flap in these cases occasionally produces either a marked emphysema or an increased inability to inflate the lungs The dyspnea is alarming and unless promptly relieved is usually fatal Atelectasis and localized emphysema may occur One bronchus may be cut off so that respiration is performed with one lung

Toxic absorption from the larynx and trachea is slight and serious toxic effects such as myocarditis and paralysis seldom occur in infections *limited* to these areas

Diphtheria of Other Parts —Diphtheria of the mouth and tongue is extremely rare and almost invariably preceded by a wound or other infection Diphtheria of the skin is rare but fatal cases have occurred It appears secondary to wounds abrasions or infections such as impetigo varicella or eczema it may rarely occur at the umbilicus in the newborn Diphtheria of the penis after circumcision and of the vulva vagina or cervix during the puerperium has been reported These may be secondary to the nose and throat infection in the same patient or occasionally primary infections brought from an outside source Diphtheria of the conjunctival sac is rare usually complicating the nasal infection Swelling and discharge are marked membrane forms on the conjunctiva and if it extends over the cornea produces permanent opacity Diphtheria of the middle ear may occur as the result of extension from the nasopharynx this is rarely a primary diphtheritic infection but follows infection by other organisms chiefly the streptococcus

Blood —There is a moderate leukocytosis rarely above 15 000 and myelocytes are occasionally present The hemoglobin and red cells usually are decreased during early convalescence The platelets are normal but occasionally may be decreased markedly during the acute stage The blood sugar rises in the early stages of severe diphtheria and the glycogen reserve is lowered There is reduced sugar utilization Later hypoglycemia occurs which gradually disappears as convalescence advances

The blood pressure in the severer cases drops during the first week and reaches its lowest level during the second week after which it gradually rises to normal Cardiac complications cause a sudden drop which may rapidly go below readable levels in fatal cases

Course —Untreated by antitoxin mild cases may rapidly subside even in a day or two but usually the disease increases in intensity up to the seventh or eighth day then if death does not supervene the symptoms gradually subside The nasal cases may persist for two to three weeks With antitoxin improvement begins within thirty six hours and the local lesion subsides in from one to seven days In severe cases secondary shallow ulceration may be seen as the membrane disappears and this may persist for one to two weeks

Complications —*Bronchopneumonia* is the most frequent complication of the laryngeal form especially when the membrane extends down into the trachea and is present in practically all fatal cases In cases of respiratory paralysis usually in the fifth to eighth week bronchopneumonia is very prone to occur *Ulceration* of the throat is not a striking feature of diphtheria It is seen only in the severe forms after clearing of the false membrane Hemorrhage from the nose or throat may be severe and persistent and require packing or other measures *Cervical adenitis* may appear in early convalescence and progress to suppuration *Otitis media* is rare and occurs chiefly in postnasal and extensive faucial cases It may occur secondary to pharyngeal paralysis *Albuminuria* is common in severe cases during the active stage Acute nephritis is rare but may follow in the second or third week and at times is severe

Paralyses occur in about 10 per cent of cases but the rate is much higher in untreated or inadequately treated patients It is a painless peripheral neuritis progressing gradually downward appearing first in the palate at the end of the first or in the second week and last in the legs often after several weeks It gradually increases and then recedes completely disappearing in days to weeks but may persist for three

to four months In the severe cases any or all of the motor nerves may be involved but due to the difference in time of onset and progression involvement is not simultaneous Sensory involvement is less frequent being seen only in the severest cases and occurring later than the motor The smooth muscle fibers are not paralyzed

The distribution of the paralysis is influenced partly by the location of the local lesion In tonsillar or pharyngeal diphtheria the palate shows the earliest and most frequent involvement and if unilateral affects the side of the more marked infection Recurrent *palatal paralysis has been seen* The first paralysis appears early, usually on the fifth to sixth day lasting a week and in unilateral infection is always on the same side The second paralysis appears in the third week and lasts two to three weeks and may be bilateral In cases infected through wounds the paralysis may be localized or appear first in muscles adjacent to the wound

The palatal paralysis produces nasal or cleft palate voice nasal regurgitation and incomplete motion of the palate Paralysis of the constrictors and the geniohyoid group produces dysphagia especially for solids and serious and even fatal choking has occurred from attempting to swallow them There is often great distress choking and gagging from the collection of saliva in the throat There may be marked or even complete anesthesia of the throat

Ocular palsy usually involves the accommodation but strabismus may occur Paralysis of the face neck trunk arm or leg may occur usually progressively but the legs are usually more strikingly affected The knee jerks are diminished or lost although at first they may be increased There is a varying degree of reaction of degeneration

Even in the most extensive cases it is rare to find any muscle except the palate in which some observable motion cannot be made out

In the late stages there may be marked ataxia especially of the legs associated with the loss of sense of position In sensory paralysis the acuity of pain sense may be diminished more than tactile sense although both are not often completely lost Perception of heat and cold is not affected Other disturbances of the sensory mechanism such as paresthesias and formication may be found

Respiratory paralysis due to phrenic damage is the only paralysis that may prove fatal and it usually occurs in the fourth to eighth week of illness

Paralysis of the larynx appears usually in the third week and causes dysphonia or aphonia Wolcott found laryngeal obstruction due to abductor paralysis in 48 of 478 cases of paralysis In laryngeal diphtheria it is difficult to distinguish toxic paralysis from local injury

Cerebral paralysis may follow diphtheria producing monoplegia or hemiplegia In our eight cases it has always been due to a thrombosis of a cerebral artery and has manifested itself as a partial or complete hemiplegia It may completely or partially disappear and is probably the only type of permanent paralysis due to diphtheria It may occur with diphtheritic paralysis concomitantly

Cardiac Complications—In about 5 per cent of patients chiefly in the severe toxic cases heart disease occurs in some form The onset is from the sixth to the twenty first day the symptoms being sudden pallor and listlessness often associated with nausea vomiting and pain in the epigastrium The blood pressure drops The epigastric pain may be marked and suggestive of an acute abdominal condition The liver is often enlarged and usually tender The area of cardiac dulness may be increased and the cardiac impulse soft and diffuse However in many cases no dilatation can be made out Vomiting may be severe and persistent but usually ceases on stopping food and fluids The pulse rate may drop remain unchanged or become rapid The first sound is softened and frequently the diastolic pause is shortened Arrhythmia is the most common finding and every type of abnormal rhythm may occur There are often rapid changes in the type of arrhythmia Electrocardiograms show in the main two types of injury (1) T wave changes (2) auriculoventricular and intraventricular block In the first recovery usually occurs while in the second except in the mild form death ensues Most deaths occur within three days after the onset it is rare to have patients die after

larynx or trachea, or of the whole pulmonary tree may be brought up

When the membrane extends down the trachea or into the bronchi, as frequently occurs, this may not be clinically evident until it has been loosened from the tracheal or bronchial wall or until it reaches the bronchioles when dyspnea may occur, usually with increased *expiratory* stridor A valvelike *flap in these cases occasionally* produces either a marked emphysema or an increased inability to inflate the lungs The dyspnea is alarming and unless promptly relieved, is usually fatal Atelectasis and localized emphysema may occur One bronchus may be cut off so that respiration is performed with one lung

Toxic absorption from the larynx and trachea is slight and serious toxic effects such as myocarditis and paralysis seldom occur in infections *limited* to these areas

Diphtheria of Other Parts—Diphtheria of the mouth and tongue is extremely rare and almost invariably preceded by a wound or other infection Diphtheria of the skin is rare but fatal cases have occurred It appears secondary to wounds, abrasions or infections, such as impetigo varicella or eczema it may rarely occur at the umbilicus in the newborn Diphtheria of the penis after circumcision and of the vulva vagina or cervix during the puerperium has been reported These may be secondary to the nose and throat infection in the same patient or occasionally primary infections brought from an outside source Diphtheria of the conjunctival sac is rare usually complicating the nasal infection Swelling and discharge are marked membrane forms on the conjunctiva and if it extends over the cornea produces permanent opacity Diphtheria of the middle ear may occur as the result of extension from the nasopharynx this is rarely a primary diphtheritic infection but follows infection by other organisms chiefly the streptococcus

Blood—There is a moderate leukocytosis rarely above 15 000 and myelocytes are occasionally present The hemoglobin and red cells usually are decreased during early convalescence The platelets are normal but occasionally may be decreased markedly during the acute stage The blood sugar rises in the early stages of severe diphtheria and the glycogen reserve is lowered There is reduced sugar utilization Later hypoglycemia occurs which gradually disappears as convalescence advances

The blood pressure in the severer cases drops during the first week and reaches its lowest level during the second week after which it gradually rises to normal Cardiac complications cause a sudden drop which may rapidly go below readable levels in fatal cases

Course—Untreated by antitoxin, mild cases may rapidly subside even in a day or two but usually the *disease increases in intensity* up to the seventh or eighth day then if death does not supervene, the symptoms gradually subside The nasal cases may persist for two to three weeks With antitoxin, improvement begins within thirty six hours and the local lesion subsides in from one to seven days In severe cases secondary shallow ulceration may be seen as the membrane disappears and this may persist for one to two weeks

Complications—*Bronchopneumonia* is the most frequent complication of the laryngeal form, especially when the membrane extends down into the trachea and is present in practically all fatal cases In cases of respiratory paralysis usually in the fifth to eighth week bronchopneumonia is very prone to occur *Ulceration* of the throat is not a striking feature of diphtheria It is seen only in the severe forms after clearing of the false membrane Hemorrhage from the nose or throat may be severe and persistent and require packing or other measures *Cervical adenitis* may appear in early convalescence and progress to suppuration *Otitis media* is rare and occurs chiefly in postnasal and extensive faucial cases It may occur secondary to pharyngeal paralysis *Albuminuria* is common in severe cases during the active stage Acute nephritis is rare but may follow in the second or third week and at times is severe

Paralyses occur in about 10 per cent of cases but the rate is much higher in untreated or inadequately treated patients It is a painless peripheral neuritis progressing gradually downward appearing first in the palate at the end of the first or in the second week and last in the legs often after several weeks It gradually increases and then recedes completely disappearing in days to weeks but may persist for three

as occurring in lymphatic and myelogenous leukemia and in aplastic and pernicious anemia as well as in syphilis

LARYNGEAL DIPHTHERIA—Croup should always be considered and treated at once as diphtheria unless the latter can be definitely excluded When associated lesions occur in the throat or nose the diagnosis of diphtheria may be made easily but when primary in the larynx recognition may be difficult without laryngeal examination When the infection in the larynx is diphtherial a characteristic membrane may not appear at once and in some cases streptococcic infections may have an exudate closely simulating diphtheria In diphtheria the signs usually show gradual progressive development but in exceptional cases progress may be very rapid

SPASMODIC CROUP is characterized by a sudden onset of croupy cough and stridor frequently at night and by frequent remissions often complete during the day Dyspnea may be variable Dysphonia and aphonia are usually absent but this is also true in diphtheria below the vocal cords The history of previous attacks is valuable Laryngeal examination shows only redness and adduction of the cords due to spasm

LARYNGISMUS STRIDULUS occurs in tetany usually associated with marked rickets The stridor is purely *inspiratory* and there is no dyspnea

LARYNGOSPASM producing stridor and croupy cough may occur in a variety of neurologic states such as poliomyelitis with bulbar involvement and basilar meningitis

EDEMA OF THE GLOTTIS due to inflammation of the epiglottis and aryepiglottic folds produces an *inspiratory* dyspnea without dysphonia and is often associated with high fever and great prostration It can be easily diagnosed by palpation or laryngoscopy Diphtheria produces supraglottic edema only when there is severe faucial involvement

RETROPHARYNGEAL ABSCESS causes only *inspiratory* stridor until the abscess is very large There is dysphagia and no dysphonia There may be cervical adenitis which is not found in laryngeal diphtheria Palpation of the postpharyngeal wall discloses the swelling

FOREIGN BODY—The sudden choking attacks which usually occur in lodgment of a foreign body may not be observed in young children and instead gradually increasing signs of obstruction may occur Laryngoscopy is important Routine laryngoscopy in cases of supposed diphtheria has repeatedly shown foreign bodies Obstructions below the suprasternal notch produce *expiratory* stridor and there is no croupy cough nor dysphonia The expiration is usually long and wheezing

THYMIC ASTHMA is rare Laryngoscopy shows a normal larynx

ACUTE LARYNGITIS due to streptococcal influenzal or other bacterial infections cannot be distinguished certainly without laryngoscopy and laryngeal cultures It is safer to give antitoxin unless it is known that the patient has a negative Schick reaction

Bacteriologic Diagnosis—Cultural diagnosis naturally has been of the utmost value in this disease Atypical cases both very severe and very mild as well as carriers would be frequently missed without it It must be noted that the presence of diphtheria bacilli in cultures from a lesion does not necessarily prove diphtheria to be present This may be readily demonstrated in diseases such as syphilis where the lesion may be accurately identified In cases such as mild tonsillitis when diphtheria bacilli are obtained demonstration of adequate antitoxic immunity is necessary In any case clinical safety suggests the accepting of diphtheria bacilli in cultures as indicating the disease until otherwise proved

When bacilli have been shown to be non virulent diphtheria may be dismissed More rapid growth for diagnosis has been secured by Brahdy by preparing the swabs with media incorporated into the cotton By this method good smears may be secured in four hours In rare instances patients with negative Schick tests exposed to diphtheria develop membranous lesions typical of mild diphtheria and show virulent diphtheria bacilli These cases are mild get well rapidly without treatment and do not develop toxic effects

CULTURAL TECHNIC—For accurate results the following details should be followed the swab should be applied only to the area of inflammation and *thoroughly* rubbed over it If there is a thick membrane it is better to

the third week of *diphtheria from* this cause Complete ultimate recovery is the rule in the nonfatal cases although a few cases may show electrocardiographic changes and varying degrees of circulatory failure for long periods Clinical evidence of marked fibrous myocarditis is rarely found although histopathologic studies would suggest it as a frequent sequel

Diagnosis —Early *diagnosis is of* the utmost importance but antitoxin should be used at once in all cases where the findings suggest diphtheria and its certain exclusion is impossible After *some experience* it is possible to decide in which cases it is *safe* to wait for cultural evidence Any swelling or membrane in the throat, croupy cough *dyspnea or postnasal* infection is sufficient reason for antitoxin treatment unless the *physician can identify* the lesion as unquestionably not diphtheria The *most significant* features are the translucent gray membrane which later becomes dense sharply defined and evenly contoured the relatively slight redness surrounding the membrane and the peculiar rather soft swelling of the throat and neck in the severer cases In the nasal cases the seromucoid, often blood tinged associated discharge with nasal obstruction is characteristic while in the laryngeal cases croupy cough dysphonia, and stridor are typical The fever is usually slight or moderate and general toxic symptoms are mild, except in advanced cases

Differential Diagnosis —Follicular or Lacunar Tonsillitis —The membrane is in multiple specks or larger masses often closely placed the redness is usually brighter, more extensive and the constitutional symptoms more marked than in diphtheria Evidence of immunity by a negative Schick test is of value A diphtheritic membrane however may start as small tonsillar specks and some observers consider this the usual picture in mild cases

Peritonsillitis —In peritonsillitis there is a bright extensive redness a firmer more tender swelling the swelling is more apt to be confined to the glands which are hard and tender and there is more dysphagia pain and difficulty in opening the mouth When fluctuation can be made out by the exploring finger the diagnosis is assured

Septic Throat and Scarlet Fever —The membrane in these conditions is apt to be whiter, with more irregular margins, and often *more friable*, ulceration is frequent and the most important characteristic finding *is a brighter*, more extensive redness beyond *the membrane* The toxic symptoms are usually severe and high fever, vomiting and delirium may be present In scarlet fever the eruption and strawberry tongue in addition to the characteristic throat and rash, usually distinguish it from diphtheria

Vincent's angina occurs invariably as a sharply defined ulceromembrane The membrane is friable has a foul odor and when *removed leaves a* dirty base Surrounding inflammation is slight or absent Swelling and glandular reaction are absent or slight and constitutional symptoms mild In addition to the faucial lesion there is usually an ulceromembranous gingivitis which may be limited to a small area, or involve the whole gingival margin The smear shows predominating *Bacillus fusiformis* and *spirochetes of Vincent*

Agranulocytosis —Membranous ulceromembranous or phlegmonous lesions of the throat may occur with neutropenia They are more notable for their variety than for distinguishing features Prostration out of proportion to the lesion persistence of the lesion and inconsistencies in the clinical appearance may suggest a blood examination which will make the diagnosis A routine white blood count is desirable in throat lesions In *monocytic angina* membranes and ulceromembranes are often distinguished with difficulty from diphtheria The slow course often a prodromal illness of a few days preceding the sore throat and the differences in the lesion may be helpful in differentiation The increased monocytes in the blood and the heterophile agglutination in the blood are important aids In many cases general glandular enlargement and splenomegaly will indicate the disease

Thrush —The white curdled milk like membrane of thrush may occur in large patches sometimes producing extensive membranes over tonsils pillars uvula and palate The surface is usually granular or matted and friable and pieces of the exudate show mycelial threads or spores

Lesions of the mucous membranes at times simulating diphtheria must be kept in mind

in many cases Rare instances occur where it is lost within one to two years The fact that the toxoid has been given should not be accepted as evidence of immunity until a subsequent Schick test is negative Reactions to the toxoid are infrequent, local and mild although slight malaise and fever on the following day may occur especially in older children Immunity develops slowly in from one to four months but may appear even after a year Nearly the same results are obtained with toxin antitoxin mixtures containing 0 1 lethal dose of toxin In older children and adults the reactions are somewhat less than with toxoid There is some sensitization to horse serum unless goat or sheep toxin antitoxin is used Alum precipitated toxoid because of its slow absorption and absence of rapid elimination may be given in a single dose Better results are obtained with two injections but at present the soluble toxoid in three doses produces optimal results Differences in absorption make alum precipitated toxoid slightly less certain than soluble toxoid

The *Schick test* is done by intracutaneous injection of 0 1 cc toxin solution containing $\frac{1}{50}$ M L D A special syringe and a 26-gauge short bevel needle are desirable The injection should produce a distinct wheal A control test is done in the same manner with a similar solution heated to destroy the toxin

The reaction to the toxin appears in twenty four to forty-eight hours increases for four to five days and varies in size from 1 to 7 cm in diameter Severe reactions may be vesiculated Subsidence begins in about a week and pigmentation followed by desquamation often results The area may be distinguished for months in some cases Reactions in the control tests result from foreign protein contained in the medium or in the bacillus and show no relation to immunity They appear in eighten to twenty four hours and usually subside in two to three days

A reaction to the toxin shows lack of immunity When the control test is negative positive and negative Schick tests are easily determined by the presence or absence of reaction When there is reaction at the control area a positive Schick test (combined reaction) *is determined by (1) the larger* size (2) the longer period to reach the height of the reaction (four to five days) and (3) the later pigmentation and desquamation If the Schick and control tests are exactly parallel the test is negative (pseudoreaction) and the patient immune Exposed children who have not been subjected to the Schick test may be protected by subcutaneous injections of 1500 to 2000 units of antitoxin This passive immunity lasts for two to three weeks This procedure may be omitted if careful daily examinations and cultures from the throat and nose are taken If the cultures are positive or if symptoms appear antitoxin should be given at once

The prevention of the spread of diphtheria requires the following procedures

1 All patients, as well as carriers should be promptly isolated

2 Isolation should prevent direct or indirect contact of the patient with others by sterilization of (1) dishes (2) linen and (3) other utensils when taken from the isolation zone and by protection of the clothes face etc., of attendants by gowns with the usual aseptic technic Sterilization should be done by boiling dry heat baking chemical disinfection with 1 per cent trikresol solution or other disinfectants or by exposure to direct sunlight for a few hours

3 The patient must be kept under these precautions until shown free of diphtheria bacilli by two or more consecutive daily negative cultures

4 Terminal disinfection while of little importance should be carried out as indicated especially on objects in intimate contact with the patient s nose and throat or with his secretions Aseptic technic in the care of the patient and concomitant disinfection during the acute and convalescent stages renders the patient s surroundings comparatively free from infection by the time the bacilli have disappeared from the mucous membranes

Treatment — *General* — The patient should be kept in bed and as free from exertion as possible not only during the acute stage but until danger of cardiac injury has subsided (at least three to four weeks) Allowing activity before this such as getting out of bed should be countenanced only *when the physician is certain that the tox*

swab the edge In laryngeal infection, if primary, the swab should be taken directly from the larynx, preferably through a laryngoscope For carriers, all the parts of the upper mucous membranes must be swabbed The swab should be well rubbed over the Loffler slant

Reliable results can be obtained only after six to eight hours incubation at 37° C and preferably after eighteen to twenty hours Negative reports should not be accepted as excluding diphtheria, even if the above details are completely followed unless repeated two to three times Positive reports do not prove that diphtheria is present but should always be so accepted until diphtheria is excluded

Prognosis —The chief factor in prognosis is the prompt administration of an adequate amount of antitoxin A few hours delay in the administration of antitoxin in a rapidly developing case may make a grave difference in the prognosis Table 1 taken from Ker is representative of a series of cases which various authors have reported

TABLE 1

RELATION OF MORTALITY IN DIPHTHERIA TO TIME OF ADMINISTRATION OF ANTITOXIN (Ker)

Day	*Patients*	*Deaths*	*Fatality rate*
First	329	5	1.5
Second	2269	77	3.3
Third	2407	165	6 8
Fourth	1612	176	10.9
Fifth	911	136	14 9

Age is an important factor The younger the patient, the higher the mortality rate the latter being especially high during the first two years of life

The location of the infection has an important influence Laryngeal infection before the use of antitoxin had a fatality rate of about 90 per cent The deaths are chiefly due to asphyxia and bronchopneumonia Faucial and nasopharyngeal diphtheria are associated with rapid absorption of toxin while infection of the anterior nares skin and other locations is rarely followed by severe toxic damage Swelling of the throat and neck rapid formation of membrane and hemorrhages denote grave danger Deaths during the first week occur usually from acute toxemia or from complicating infections During the second and third week deaths are from myocarditis or secondary infection, and later, especially about the fifth to eighth week from respiratory paralysis

Mortality —Before the discovery of antitoxin the fatality rate in diphtheria was about 35 per cent and in laryngeal cases about 90 per cent but since its discovery the mortality is approximately 5 per cent and in the laryngeal cases 15 per cent These figures are influenced by early treatment and in the laryngeal form by many factors in management The community death rate has dropped steadily for a long period and since active immunization, has reached a low level Table 2 gives the mortality for Massachusetts in five year periods

TABLE 2

DEATH RATE PER 100 000 POPULATION IN MASSACHUSETTS

1870–1874	49 9	1905–1909	22 1
1875–1879	154 6	1910–1914	17 1
1880–1884	106 9	1915–1919	18 0
1885–1889	84 8	1920–1924	14 6
1890–1894	64 0	1925–1929	6 5
1895–1899	51.2	1930–1934	2 6
1900–1904	35 4	1935–1938	0 5

Prophylaxis —Control is practicable only by active immunization It is not essential to procure immunity in 100 per cent of the population as experience has shown that if 85 per cent are immune they will prevent an epidemic the non immunes being protected by the immunes

Immunity is secured by administering toxoid or toxin antitoxin mixtures to all children in early life preferably between six months and one year of age Toxoid or anatoxin is rapidly displacing the toxin antitoxin It does not sensitize to foreign serum but produces slightly more reactions in adults and older children The toxoid is given in three doses of 0.5 1, 1 cc subcutaneously at intervals of three to four weeks A Schick test should be done in six months and if immunity has not developed another series of toxoid injections should be given While the highest value of active immunization is secured by applying it in the latter part of the first year, it may be used with valuable effect later in the school age and in adults who are brought especially into contact with this disease Immunity so secured lasts for many years and probably for life

in many cases Rare instances occur where it is lost within one to two years The fact that the toxoid has been given should not be accepted as evidence of immunity until a subsequent Schick test is negative Reactions to the toxoid are infrequent local and mild although slight malaise and fever on the following day may occur especially in older children Immunity develops slowly in from one to four months but may appear even after a year Nearly the same results are obtained with toxin antitoxin mixtures containing 0 1 lethal dose of toxin In older children and adults the reactions are somewhat less than with toxoid There is some sensitization to horse serum unless goat or sheep toxin antitoxin is used Alum precipitated toxoid because of its slow absorption and absence of rapid elimination may be given in a single dose Better results are obtained with two injections but at present the soluble toxoid in three doses produces optimal results Differences in absorption make alum precipitated toxoid slightly less certain than soluble toxoid

The *Schick test* is done by intracutaneous injection of 0 1 cc toxin solution containing $1/50$ M L D A special syringe and a 26 gauge short bevel needle are desirable The injection should produce a distinct wheal A control test is done in the same manner with a similar solution heated to destroy the toxin

The reaction to the toxin appears in twenty four to forty eight hours increases for four to five days and varies in size from 1 to 7 cm in diameter Severe reactions may be vesiculated Subsidence begins in about a week and pigmentation followed by desquamation often results The area may be distinguished for months in some cases Reactions in the control tests result from foreign protein contained in the medium or in the bacillus and show no relation to immunity They appear in eighten to twenty four hours and usually subside in two to three days

A reaction to the toxin shows lack of immunity When the control test is negative positive and negative Schick tests are easily determined by the presence or absence of reaction When there is reaction at the control area a positive Schick test (combined reaction) is determined by (1) the larger size (2) the longer period to reach the height of the reaction (four to five days) and (3) the later pigmentation and desquamation If the Schick and control tests are exactly parallel the test is negative (pseudoreaction) and the patient immune Exposed children who have not been subjected to the Schick test may be protected by subcutaneous injections of 1500 to 2000 units of antitoxin This passive immunity lasts for two to three weeks This procedure may be omitted if careful daily examinations and cultures from the throat and nose are taken If the cultures are positive or if symptoms appear antitoxin should be given at once

The prevention of the spread of diphtheria requires the following procedures

1 All patients as well as carriers should be promptly isolated

2 Isolation should prevent direct or indirect contact of the patient with others by sterilization of (1) dishes (2) linen and (3) other utensils when taken from the isolation zone and by protection of the clothes face etc of attendants by gowns with the usual aseptic technic Sterilization should be done by boiling dry heat baking chemical disinfection with 1 per cent trikresol solution or other disinfectants or by exposure to direct sunlight for a few hours

3 The patient must be kept under these precautions until shown free of diphtheria bacilli by two or more consecutive daily negative cultures

4 Terminal disinfection while of little importance should be carried out as indicated especially on objects in intimate contact with the patient s nose and throat or with his secretions Aseptic technic in the care of the patient and concomitant disinfection during the acute and convalescent stages renders the patient s surroundings comparatively free from infection by the time the bacilli have disappeared from the mucous membranes

Treatment — *General* — The patient should be kept in bed and as free from exertion as possible not only during the acute stage but until danger of cardiac injury has subsided (at least three to four weeks) Allowing activity before this such as getting out of bed should be countenanced only when the physician is certain that the tox

emia has been comparatively mild This is not easily determined The diet should be liquid and should contain adequate carbohydrates sufficient vitamins, especially B and C and a minimum of proteins During the acute stage a liquid diet is preferable

Acute Myocarditis—The most important factor is *complete rest, constant horizontal* position with the head low, and avoidance of all unnecessary handling and activity Nausea and vomiting frequently require starvation for a period and 50 per cent glucose solution intravenously, usually 25 to 50 cc should be given two to four times daily One unit of insulin for each 2 5 Gm of glucose should be given subcutaneously It may be necessary to continue this medication for more than a few days Morphine subcutaneously, should be given to secure rest and quiet as needed Cardiac stimulants have little value Digitalis may rarely be of aid but it may do harm by increasing the heart block Caffeine sodiobenzoate is of value in vasomotor collapse

Paralysis—Usually no treatment is required There are no postural problems due to contractures and recovery is the invariable rule Permanent paralyses are due to other causes such as thrombosis and are rare Respiratory paralysis is best treated in a respirator and if marked such recourse is essential Changing the posture to avoid hypostatic pneumonia is important If there is inability to swallow it is helpful to turn the patient on the face to avoid the constant choking from saliva If paralysis of the swallowing muscles is associated with respiratory paralysis suction can be used to minimize the discomfort Atropine may be used to reduce salivation Feeding must be done with a stomach or duodenal tube through the nose or the mouth

Antitoxin Treatment—The greatest advance in the treatment of diphtheria has been the discovery of antitoxin and its effectiveness depends on administration of an adequate amount early in the disease Patients treated on the first day of infection practically always recover but the mortality rises with each day s delay

The clinician should administer at once adequate antitoxin to every case of inflammation of mucous membranes in a child unless he can determine with sufficient certainty either that the condition is *not diphtheria* or that delay for a complete diagnosis will not endanger the patient Antitoxin has no effect on the cardiac damage or paralysis after they have appeared The total dosage should be given at once In severe cases the intravenous route is advisable while in milder cases intramuscular injection is satisfactory preferably into the upper gluteal region The dose must be adjusted to the amount of toxemia, which is best indicated by the severity of the local inflammation and the rapidity of advancement Park varies the dosage with the weight of the patient from 150 to 600 units per pound of weight in mild cases to 1000 to 6000 per pound in the severe ones In Denmark and at the South Department, Boston City Hospital very large doses are favored For mild cases 5000 units are given for moderate cases 10 000 to 20 000 units for severe cases 30 000 to 50 000 units and in malignant cases as high as 100 000 units or more

The effect on the local process will be observed within twenty four to thirty six hours Friedemann has seen the first improvement as late as the third day The swelling begins to subside, the membrane bleaches and loosens at the edge or shrinks the discharge ceases and the temperature drops The patient often feels better before the local improvement is seen Even after enough antitoxin has been given the swelling and membrane may spread rapidly for twenty four to thirty hours or if the membrane is removed it may re form due to toxin already fixed in the tissues and not influenced by antitoxin

Serum Sickness and Shock—*Reactions* to horse serum may follow the administration of antitoxin They occur in about 15 per cent of cases This reaction is influenced by the dosage small doses producing few reactions while a dosage of 100 cc will excite a reaction in about 90 per cent of cases For reasons not entirely clear antidiphtherial globulins are less likely to cause reactions than antiscarlatinal globulins

Sudden *shock* with substernal oppression dyspnea cyanosis angioneurotic edema and extensive urticaria may occur in persons sensitive to horse serum Rarely there is a fatality the incidence being about 1 in

25 000 to 35 000 cases The danger can be in large part predetermined by tests although it is possible that these may be misleading Sensitization tests should be performed by either the intracutaneous or conjunctival method The conjunctival test seems slightly less sensitive than the intradermal although this is not universally agreed and consequently a positive test is more conclusive

The Intracutaneous Test —A solution of horse serum or the serum to be used is injected *intracutaneously* in a dose of 0 01 to 0 001 cc Positive reactions appear usually within two to five minutes and occasionally within fifteen minutes manifested by redness and a spreading wheal 1 to 2 cm or more in diameter with pseudopod formation A history of allergy in the patient is important even though he may not be sensitive to horse serum

The conjunctival test is done by dropping one drop of serum (1 to 10 dilution) into the sac Positive reactions appear within five minutes with itching redness and swelling of the conjunctiva and lids If marked the reaction can be abated by a drop or two of 1 1000 solution of adrenalin dropped into the eye

All patients showing positive reactions do not react unfavorably to serum However fatal results from serum in cases with mild skin reactions have been reported

If serum must be used in a patient showing a positive allergic reaction and if there is no antitoxic serum of a type to which he is not susceptible desensitization should be done by giving subcutaneously gradually increasing doses at fifteen to thirty minute intervals starting with the test dose Each subsequent dose may be doubled but if a reaction appears the next dose and subsequent doses should not be increased until no ill effect results from its use

Adrenalin should be ready to administer if symptoms are severe Adrenalin is often given with the serum or five minutes preceding its administration and is of definite value in protecting against reactions

It may be impossible to desensitize some patients and some observers believe that it is impossible to rapidly desensitize ' atopic cases They contend that hypersensitivenes acquired by previous contact with the serum does not produce fatal anaphylactic shock and that fatal shock occurs only in case of spontaneous hypersensitiveness (atopy)

Serum sickness appears after an incubation period usually of six to twelve days occasionally up to twenty-one days It may appear in sensitized persons in a few minutes or during the first day Urticaria is the commonest symptom and may be local at the site of injection or general Multiform erythema is less common and usually appears in a week It may be morbilliform circinate or rarely scarlatiniform Angioneurotic edema especially of the face and hands may occur usually associated with urticaria Adrenalin in doses of 10 to 15 minims given subcutaneously relieves urticaria for one to two hours and may be repeated as needed It may produce sudden nervousness tremor tachycardia and even eye symptoms in hypersensitive patients Local sedatives such as calamine lotion menthol alcohol solutions and soda bicarbonate may be used and general sedatives such as phenobarbital may give relief The patient should be kept cool and quiet

Arthralgia usually without signs of active inflammation is a distressing serum reaction It is apt to be multiple lasting three to four days or rarely longer and pain is chiefly due to motion Immobilization gives relief

The Arthus reaction may occasionally appear at the site of injection of serum within twenty four hours as a reddened tender swollen area simulating an infectious cellulitis It reaches its height in two to three days and usually subsides in a week Local necrosis may occur in severe cases It is apt to appear in patients who have previously had serum We have seen over 25 per cent of a large group of boys develop this reaction on a second injection of serum one week after the first

Local Treatment —Local treatment has no effect upon the toxic damage and may be actually harmful Throat irrigations with warm salt solution or 25 per cent glucose solution may be used if they do not tire the patient Nasal irrigation is likely to increase the incidence of otitic infection Suction with a small catheter will often give marked relief

Laryngeal Diphtheria —In addition to the prompt administration of antitoxin this form frequently requires mechanical relief of ob

struction due either to membrane or swelling but usually to both Spasm usually plays no part and a steam tent may increase the dyspnea more than cold outdoor air Exertion, such as crying walking and talking increases the dyspnea since the need of oxygen cannot be entirely met and the greater respiratory effort further increases the oxygen demand

When obstruction is due to the membrane relief may be obtained by suction through the laryngoscope with special tubes or by swabbing or, less rapidly by forceps The membrane is readily detached from the *trachea and slightly less so from the larynx* It may re form in six to twelve hours and require removal and this may recur up to twenty four or thirty six hours *after* antitoxin has been given If swelling is the main cause of obstruction an intubation tube may be inserted with complete relief The degree of stenosis requiring this is difficult to define It should not be postponed until fatigue or cyanosis appears Increasing obstruction leads to physical exhaustion partial anoxemia acidosis fluid and food starvation hypoglycemia and the accumulation of mucopurulent material below the stricture and these factors strikingly predispose to pneumonia When a child at rest shows stridor and use of the accessory muscles of *respiration intubation should be done* Sedatives if used must be given with great care A patient exhausted before intubation often goes to sleep at once thereafter and should not be fed by mouth or disturbed until he has had a breathing spell and regained active reflexes

Low obstruction may occur in the trachea or bronchi from partial detachment of a membrane or by attempts to expel a cast from below This may appear suddenly with complete obstruction requiring immediate treatment or it may produce a gradually increasing dyspnea which is distinguished from pneumonia or toxic dyspnea by the characteristic stridor These low obstructions are best relieved by suction through the laryngoscope or bronchoscope

The intubation tube is removed in four to seven days If swelling persists reinsertion may be needed using a smaller size If antitoxin has been properly given continued stenosis is due to *secondary infection* or trauma and if persistent for two to three weeks may indicate tracheotomy

Feeding should be with liquids and semisolids and patients often swallow better in the sitting position Nasal feedings are usually unnecessary Fluids such as glucose and salt solution may be given intravenously or by hypodermoclyses

TRACHEOTOMY—Tracheotomy for relief of diphtherial obstruction has been largely replaced in the United States by intubation It must be used however, when the obstruction is above the larynx as in severe faucial diphtheria In some cases of extension of the *membrane far down the bronchial tree* it has an advantage in allowing easier instrumentation with bronchoscopes but usually the long suction tubes make this unnecessary *In cases where laryngeal tubes or in*struments are not available tracheotomy may be imperative The indications are the same as for intubation and Trousseau emphasized the harm of waiting until the last moment before resorting to the operation

Tracheotomy patients require constant supervision and the inner tube must be removed and cleaned frequently It must be boiled before reinsertion If obstruction occurs below the tube the whole tube may be removed the wound held open by spreaders and the obstruction removed by *suction swabbing or forceps* Relief may be obtained by suction with a catheter passed through the tube Lubrication of the trachea with sterile vegetable oil such as oil of sweet almonds may assist in coughing out secretions The tube is kept until the stenosis subsides a point which can be ascertained only by removing the tube from time to time

Chronic Stenosis of Larynx—Persistent stenosis results usually from secondary infection chiefly streptococcal which invades the laryngeal tissue and causes ulceration chondritis or perichondritis and sometimes peritracheal abscess or it may follow pressure necrosis from too large tubes or trauma in inserting or removing the tube Some observers ascribe it to paralysis It is much more common in infections other than diphtheria Tenderness of the laryngeal cartilages is found on palpation when there is chondritis This symptom is not present in simple diphtheria of the larynx If any of the causa

tive factors above mentioned is discovered tracheotomy, usually low, should be done or if stenosis persists even without obvious cause for two or three weeks tracheotomy is to be seriously considered After tracheotomy, the larynx should be left alone until healing is completed when dilatation or other operative treatment may be undertaken

Carriers.—The treatment of carriers is unsatisfactory and no specific is available If there is a definite focus of infection in the tonsils tonsillectomy will usually be followed by disappearance of the diphtheria bacilli from the throat Before tonsillectomy, cultures should be taken from all the various areas for several days to determine the point or points of infection These are frequently limited and if confined to the tonsils recovery after tonsillectomy may be confidently predicted Outdoor living and exposure to the sun are of great value and the carrier state is less frequent in the summer Sinus infection is a frequent cause of the carrier state and should be treated if present Subacute pharyngitis can often be treated successfully with a 5 per cent silver nitrate solution

A great variety of antiseptics are used such as gentian violet 2 per cent mercurochrome and various acids applied by swabbing or sprays The frequent failure of these is probably due to the difficulty of reaching the organisms in the throat or nose Persistent use of germicides or simply persistent waiting may be followed by success

Treatment of the carrier is not indicated if the organisms are nonvirulent and this should be determined at the outset A great majority of clinical cases rid themselves of the bacilli within two weeks after recovery from diphtheria and the contact of these cases with other diphtheria patients even for long periods rarely induces the carrier state

TETANUS

(*Lockjaw*)

Definition.—Tetanus or lockjaw is an infectious disease in which the symptoms are due to the toxin produced by the causative organism *Clostridium tetani*

History —The manifestations of tetanus are so *dramatic that it has been recognized as a* clinical entity for centuries In fact, both the systemic and the regional forms of the disease are clearly described in the writings of Hippocrates The transmissibility of tetanus was shown in 1880 and the actual causative agent was identified by Nicolaier in 1884 An immense amount of study was devoted to this malady during the twenty years following the isolation of the *Clostridium tetani* This work culminated in the experiments of Meyer and Ransom which seemingly proved that the clinical manifestations of tetanus were due to the passage of the tetanus toxin up the motor neurons of the central nervous system This theory was universally accepted until the last decade when it was challenged and probably refuted by Abel and his coworkers who claimed that the toxin reached the central nervous system by the blood stream The other great milestones in the mastery of this frequently fatal infection were the development of specific antitoxin (Behring and Kitasato) and the production of toxoid for active immunization

Incidence —Virtually all warm blooded animals are susceptible to tetanus The disease is found wherever the soil is contam

inated by animal or human excreta Recent inquiry into the occurrence of tetanus spores on the pavements of Baltimore show an incidence of 17 per cent The number of deaths reported in the United States in 1936 were 1088 but doubtless there were many unreported cases Regions of the country in which the soil has been intensively fertilized have a distinctly higher incidence of tetanus than less cultivated areas During the early months of the first World War the occurrence of the disease among the British Expeditionary Forces was exceptionally high (32 per 1000 wounded) The mandatory administration of tetanus antitoxin to all wounded soldiers corrected this condition so that when the American troops became active in France, only 36 among the 224 089 wounded developed tetanus (0 16 per 1000)

Etiology—The etiologic agent is always the same but the manner in which the spores or the organisms enter the body is not always apparent There are numerous ways in which this may occur Frequently an insignificant wound suffices to admit the organism Sometimes it is impossible to find the point of entrance or the locus of infection Contamination of the umbilicus of the new born is still an all too frequent occurrence The planting of spores into clean operative wounds during dust storms has become a real source of infection in certain parts of the United States Compound fractures the wounds from blank cartridges embedded splinters and puncture wounds of the feet are frequently the forerunners of tetanus Bee stings insect bites burns hypodermic injections and bed sores contaminated with fecal matter have been known to be sources of this infection The mere deposition of spores into the tissues does not suffice to produce clinical manifestations of tetanus There must be concomitant necrosis of tissue due to trauma or a foreign body or an associated pyogenic infection to facilitate the growth of the *Clostridium tetani* The spores germinate only where there is diminished oxygen tension

Bacteriology—*Clostridium tetani* is a slender slightly motile rod from 2 to 5 microns in length Various strains differ in their pathogenicity They tend to grow singly and the development of a spherical spore gives the sporulative form a characteristic squash racket appearance *Clostridium tetani* perpetuates itself outside the animal body and spores are found in earth, manure and putrefying liquids They are found in the intestines of many ruminants horses and herbivora as well as in the stools of humans Bauer and Meyer found that approximately one in every four specimens of human feces contains tetanus spores The spores are unusually resistant to the methods commonly used to kill bacteria Mercurial preparations cannot be relied upon for this purpose formaldehyde is the most effective of the commonly used antiseptics When sterilization by heat is used one cannot rely upon boiling to destroy the spores but must autoclave the material to be sterilized at fifteen pounds pressure for twenty minutes (121° C)

The toxin produced by *Clostridium tetani* is probably the most potent water soluble poison known to man The strength of the toxin varies according to the strain of the organism used and also according to the culture medium One of the most potent toxins ever obtained has been prepared by Brewer using a modified Maclean technic This toxin was so strong that $1/_{000\,000}$ of a cc killed a 20 gram mouse in two hours The most interesting factor concerning this particular toxin is that the toxoid made from it evokes a very high immunity without producing any demonstrable antitoxin in the blood of guinea pigs

Bacteriologic Examination for Clostridium tetani Although *Clostridium tetani* is one of the easiest organisms to identify the actual isolation from surgical material presents some difficulties due to the small number of organisms usually present in wounds and the fact that the foci of infection are often small or even insignificant Debrided material should be obtained from the depth of the wound and placed into thioglycolate and cooked meat medium Duplicate cultures should be made and one set heated to 80° C for twenty minutes to kill off all organisms except the spores Then both sets of tubes should be incubated forty eight to seventy two hours and examined for gram positive bacilli with round terminal spores *Clostridium tetani* sporulates better in cooked meat medium if only a few organisms are present however growth will be initiated more read

ily in the thioglycolate medium Blood agar plates or thioglycolate agar plates should be made at this time and isolated colonies may be picked to insure pure cultures

Pathogenesis —Until the last decade there were two cardinal theories concerning tetanus that were widely accepted The first was the unitary theory which held that the disease was solely one of the central nervous system The second was the nerve carriage theory, propounded by Meyer which maintained that tetanus toxin unlike all other water soluble toxins reached the central nervous system through the peripheral nerves Abel questioned the correctness of both of these theories and drew attention to the fact that the theory of neutral transport of tetanus toxin rested on several unproved assumptions In addition to his logistic objections Abel demonstrated the production of local tetanus in experimental animals by the intramuscular deposition of minute quantities of tetanus toxin at multiple points As little as $\frac{1}{8000}$ of the usual lethal dose of toxin if placed in each of forty different places in the muscles of a hind limb of an animal renders that limb rigid for several weeks This fact however is indirect evidence of the local action of tetanus toxin subsequently Harvey showed by oscillographic studies that the site of action in local tetanus is at the neuromuscular end organ

At the same time a successful effort was made by Abel s associates to produce separately the other cardinal manifestation of tetanus namely clonic convulsions To do this minute quantities of tetanus toxin were put into an anterior horn of the dog s spinal cord It was found that following the injection there is a latent period free from any detectable changes The deep reflexes then become hyperactive to the slightest sensory stimulus It is possible to produce clonic movements in such a limb by gently blowing one s breath upon it No evidences of unyielding rigidity (local tetanus) are observed in this experimentally produced central form of the disease It was during the performance of these experiments that a wholly unexpected discovery was made namely that all of the animals died despite the fact that the amount of toxin injected into the lumbar cord was only a fraction of the ordinary intravenous lethal dose It was found that the intraspinal injection of as little as $\frac{1}{400}$ of the usual lethal dose is always followed by the death of the animal even though the toxin is placed in a nonvital center such as the lumbar cord

In a series of experiments the relative effectiveness of antitetanic serum when it is administered by various routes was studied It was found that the intrathecal route is more effective than any other in animals with early, mild or moderate symptoms In animals with very severe symptoms no form of therapy and no amount of antitoxin availed to save life This result is in keeping with the observation that once a lethal quantity of tetanus toxin has been fixed by the central nervous system no amount of antitoxin will prevent death It must be borne in mind however that severe symptoms can result from the fixation of less than a full lethal amount of toxin Consequently the presence of tetanic convulsions does not justify a physician in withholding vigorous treatment

Our concept of the pathogenesis of tetanus is that the organisms multiply in necrotic tissue or in the presence of concomitant infection The presence of spores of *Clostridium tetani* in a sterile wound will not cause tetanus When multiplying the clostridia liberate a water soluble substance that diffuses through the adjacent skeletal muscles and acts on the neuromuscular end organs to cause a state of maintained contraction This may persist for months after which time the muscles return to a normal state Some of the toxic substance pas es into the lymphatics and blood stream from which a part is taken up by the specifically reactive cells in the cord and medulla and in the motor end organs of the skeletal muscles In the central nervous system the toxin is probably altered to form a secondary substance that is not neutralized by antitetanic serum This secondary substance circulates in the blood stream and seems to cause death by interference with some essential part of the respiratory mechanism Once a lethal amount of this hypothetical toxin has been formed no known treatment will save the life of the animal

Symptoms —*Types* —There are two main forms of the disease in man generalized

tetanus and localized tetanus In most cases the former alone is recognized, although if carefully sought for, one can find a fair number of patients showing both forms Instances of *local tetanus* occurring without any generalized seizures have become increasingly frequent following the prophylactic use of antitetanic serum This occurs because the quantity of antitoxin sometimes is sufficient to neutralize the toxin in the blood but insufficient to counteract the toxin bound in the tissues near the site of injury The characteristic manifestation of local tetanus is a persistent and unyielding rigidity of a group of muscles This state may continue for weeks or months and then gradually disappear without leaving any residual change It is less likely to be fatal than other types of tetanus *Cephalic tetanus* is the name given to the particularly severe form resulting from injuries about the head *Tetanus neonatorum* is self explanatory

Incubation Period—In most patients this period is usually from five to ten days Occasionally it may be as short as three days or as long as three weeks In many instances it is impossible to determine the time of the initial infection Occasionally generalized tetanus develops despite the administration of a prophylactic amount of antitetanic serum When this occurs the incubation period is usually from two to three weeks

Premonitory Symptoms—In man the presenting symptom of tetanus is usually stiffness of the jaw Frequently this is the only early symptom although restlessness irritability stiffness of the neck difficulty in swallowing may herald the onset of the illness Stiffness of the arms or legs headache convulsions fever or chilliness are occasionally the initial evidences of the disease The importance of assuming that stiffness of the jaw is due to tetanus cannot be over emphasized It is always wise to act as if this is so until some other cause for the stiffness is shown to exist

Later Symptoms—As the disease progresses the muscles of the neck and back become rigid and the stiffness in the jaws is replaced by actual difficulty in opening them This condition called trismus is rendered more marked by reflex stimulation when the patient attempts to eat or drink The face assumes a characteristic expression the so called sardonic smile (risus sardonicus) which results from spasm of the facial muscles and the involuntary raising of the eyebrows The abdominal and lumbar muscles may assume a completely rigid state The contraction of the back muscles is often so great that opisthotonos occurs The rigidity of the abdominal muscles has occasionally led to errors in diagnosis One of the most characteristic features of general tetanus is the development of painful convulsions These are precipitated by relatively slight stimuli such as jarring of the patient's bed or an unexpected noise Profuse sweating accompanies the seizures and the viselike constriction of the chest muscles renders the patient unable to cry out Dysphagia is usually present and interferes seriously with nutrition Cyanosis and asphyxia sometimes result from spasms of the respiratory muscles or glottis The pulse and respiratory rates are increased and the temperature commonly rises from 2 to 5° F Death sometimes occurs from spasm of the respiratory muscles More frequently however the immediate cause of death is not apparent There is frequently sudden termination of breathing although the heart continues to beat for several minutes

Differential Diagnosis—Ordinarily the diagnosis of tetanus is not difficult Confusion occurs only in the initial stages of the disease when stiffness of the neck muscles *or of the jaw might be attributed to* some other condition The early symptoms of meningitis sometimes simulate the beginning of tetanus An impacted and infected third molar tooth may cause trismus Rarely peritonsillar abscesses and cellulitis may cause mild spasms of the glottis and throat muscles which to the uninitiated might suggest tetanus The typical position assumed by the hands and feet in the spasms of tetany rarely gives rise to confusion with the tonic contractions of tetanus In tetany there is no involvement of the jaws or lumbar muscles Strychnine poison at times closely resembles tetanus but rarely involves the muscles of the jaw and in strychnine poisoning the muscles of the trunk and neck are relaxed between spasms

Prognosis—The outlook in cases of generalized tetanus is always grave even in the best hospitals the death rate is frequently

more than 50 per cent There is one group of patients for whom no form of treatment will prevent a fatal outcome There is another group who will recover without specific therapy There is an intermediate group in whom the issue of life or death is determined by prompt diagnosis and adequate treatment When the incubation period is more than nine days the prognosis is rather favorable A more reliable indication however is the length of the interval between the initial symptoms and the occurrence of convulsive seizures The longer this period is the better the prognosis When a patient develops tetanus in spite of having had a prophylactic injection of antitetanic serum the course of the disease is likely to be mild and the chances of recovery very good

Prophylaxis —*Passive Immunization* —The efficacy of prophylactic injection of 1500 units of antitetanic serum is clearly demonstrated in the figures quoted in a preceding paragraph on the incidence of the disease The use of antitetanic serum has prevented the development of hundreds of cases of tetanus but it is not an entirely satisfactory procedure largely because there is no way of telling whether or not one should give antitoxin for a particular injury Every surgeon has had the experience of seeing tetanus develop from a seemingly insignificant wound yet one hesitates to give antitetanic serum to every person with a trivial injury because of the frequently severe reactions that follow the use of serum In addition to malaise serum sickness and anaphylactic reactions instances of peripheral nerve palsies have been reported Furthermore passive immunization with antitetanic serum lasts for only a week or ten days Consequently in cases of severe injury or secondary operations it is necessary to repeat the injection

A common mistake in the use of antitetanic serum is that the dosage is frequently calculated in proportion to the age of the patient Obviously this is a mistake because a small child may have a wound harboring *Clostridium tetani* and producing a great amount of toxin and an adult may have a wound with few organisms producing very little toxin Consequently since antitetanic serum is given to neutralize the toxin formed in a wound the dosage should not be proportional to the age of the patient During the first World War it was customary to give the second dose of antitoxin while the patient was under general anesthesia It seems that this procedure lessens the chance of occurrence of severe reactions Finally the cost of antitetanic serum is a real deterrent to its use Some municipalities provide practitioners with the serum for indigent patients but often the cost of the injection has to be borne by the doctor

Active Immunization —Active immunization against tetanus has been thoroughly studied during the past decade by Ramon and his associates at the Pasteur Institute The medical profession of all countries except France was slow to appreciate the importance and effectiveness of this procedure The Second World War however afforded the stimulus necessary to awaken a very keen interest in it Two kinds of tetanus toxoid have been prepared the plain and the alum precipitated In the United States standards for the potency of each have been set by the National Institute of Health The alum precipitated toxoid appears to produce a better antitoxin response in the patient The method of administering tetanus toxoid is as follows

An initial dose of 1 cc is given subcutaneously In most instances this produces no appreciable amount of antitoxin in the blood At an interval of from one to three months later a similar injection is given and within ten days there is detectable antitoxin in the blood The amount of this antitoxin is practically always sufficient to protect against an ordinary infection If however a third injection of toxoid is given at an interval of from one to three months the titer of antitoxin in the blood rises rapidly and persists for months The exact period for which protection is afforded by three injections of toxoid is not accurately known because this substance has not been available long enough Numerous authors have reported the presence of appreciable amounts of antitoxin in the blood of patients months after a basic course of toxoid has been given

Unfortunately there is no rapid method of measuring a patient s immunity against tetanus at present it is necessary to carry out a bio assay of the patient s serum in guinea pigs This is time consuming and ex

pensive Furthermore we do not know the minimal amount of antitoxin in the blood that will afford certain protection It is known, however that a prophylactic dose of antitetanic serum gives ample protection in the great majority of injuries and that the titer of antitoxin in the blood of an average adult following the usual dose of 1500 units of antitoxin is from 0 1 to 0 2 of a unit It would seem, *therefore* that such a level gives fair assurance of adequate protection Following the production of a state of active immunity it is very likely that the level of circulating antitoxin is not an accurate indication of the existing tissue immunity It is entirely possible that a patient who has had a basic course of three injections of toxoid might after some time not have any detectable *antitoxin in his blood nevertheless* this patient would probably have adequate immunity It is certain that the ability of such a patient to produce large amounts of antitoxin quickly following a fourth injection of toxoid is suggestive of an existing immunity

Reactions —All of the early workers in the field of active immunization against tetanus reported either no reactions or an exceedingly small percentage of reactions following the use of toxoid For instance Whittingham reported that only fourteen reactions of any kind were noted following the immunization of 61 000 soldiers two of these *fourteen reactions were anaphylactic* and twelve were classed as constitutional Gold found only two cases of urticaria occurring in *1700 patients immunized with* alum precipitated toxoid During the summer of 1941 however an altogether unexpected outbreak of severe reactions appeared In some places the incidence was as high as 25 per cent These reactions followed the injection of both the plain and the alum precipitated toxoid and occurred *after* the first as well as after subsequent injections An intensive study was undertaken to determine the cause of this unfortunate occurrence It has become apparent that the use of incompletely digested peptone in the media growing the *Clostridium tetani* was responsible for these reactions The technique of Brewer provides a highly potent toxin practically free from proteins

Results —The war which has now spread around the world has already afforded indisputable proof of the effectiveness of active immunization with tetanus toxoid Practically all the soldiers and horses of the French fighting forces were protected before hostilities commenced Only one soldier is known to have developed tetanus and his case was described as of mild local character Following the campaign in Flanders *there were eight British soldiers in whom* clinical tetanus was recognized These eight were in a group of 1800 wounded who had elected to omit injections with toxoid Among 16 000 who were similarly wounded but immunized not a single instance of tetanus was recorded Finally, it must be emphasized that tetanus is a preventable disease The importance of immunizing children farmers artisans and military personnel *cannot be overemphasized*

Treatment —Every effort must be made to establish the diagnosis of tetanus at the earliest possible time and to commence treatment as soon as it is certain that the patient is not hypersensitive to horse serum Patients with suspicious trismus should be admitted to a hospital and examined at frequent intervals

There are *three main objectives* in the treatment of tetanus *first* one must make every effort to prevent additional toxin from reaching the central nervous system, second the source of toxin must be removed third *the patient must be given rest* To accomplish the first purpose one should give an initial intravenous injection of 50 000 units *of antitetanic serum for the purpose* of neutralizing all of the toxin in the body which is still free and unaltered Obviously it is impractical to try to estimate how much toxin is present in any given patient but 50 000 units of antitetanic serum are sufficient to counteract the toxin in any patient who *has a chance of recovery* It seems unnecessary to give enormous doses of antitoxin for it has been shown experimentally that if one full lethal dose has been fixed and altered by the central nervous system a million neutralizing doses of antitoxin will not save the animal It must be emphasized *however that one cannot* tell whether the symptoms of central nervous system intoxication are due to a fraction of a lethal dose or to several such doses Therefore it is

imperative to give a fairly large initial intravenous dose of antitoxin and thereafter to give daily injections of 5000 units to insure the neutralization of any additional toxin that may be absorbed At the time of the intravenous injection it is important to give an intrathecal injection of from 15 000 to 20 000 units of antitetanic serum With children or with patients having severe opisthotonos it is wise to do this under general anesthesia The serum may be given either by lumbar puncture or intracisternally and of course should be administered slowly Severe and fatal reactions following the intravenous or intracisternal injection of serum have been described In none of our animals has such a reaction occurred nor has Vener reported fatal reactions in any of the seventy five patients he treated with intrathecal injections It is highly desirable that a more refined and stronger antitetanic serum be prepared to minimize the possibility of untoward reactions

Following the intravenous treatment the tissues around the infected wound should be infiltrated with approximately 10 000 units of antitetanic serum in preparation for *wide excision of the wound* This excision should be done an hour or so later and the wound left open The saturation of the tissues adjacent to the wound with antitoxin effectively prevents the dissemination and absorption of toxin at the time of operation

The *control* of *convulsive seizures* in tetanus is always a major problem The suggestion that this be accomplished by the use of sufficient amounts of chloral paraldehyde or ether oil per rectum is based largely on experimental work For certain species it seems clear that drugs which are respiratory depressants shorten the life of animals having tetanus Surprisingly large amounts of paraldehyde (from 10 to 40 cc per rectum every three hours) can be given to human beings without harm When necessary the drug can be administered in normal salt solution by the continuous intravenous drip method There are a few cases of tetanus in which death is due to laryngeal spasm When severe stridor occurs it is wise to perform a tracheotomy and if necessary maintain respiration by artificial means The use of an oxygen tent is of benefit in all severe cases of the disease

It is of fundamental importance of course to see that patients with tetanus are kept in fluid and electrolytic balance and that they are given adequate nourishment To do this it is often necessary to depend upon a liquid diet of high caloric value Frequently this has to be administered by an indwelling gastric tube passed through the nares

TYPHOID FEVER

Definition —Typhoid fever is an acute generalized infection caused by the *Eberthella typhosa* Pathologically the lymphoid tissues of the body show the greatest changes there are hyperplasia and ulceration of Peyer s patches and the solitary lymph follicles of the intestinal tract swelling of the mesenteric lymph nodes and spleen The clinical manifestations variable in degree are high fever slow pulse a rose-colored eruption abdominal tenderness and enlargement of the spleen

History —A continued fever associated with delirium has been recognized since the time of Hippocrates but not until 1820 was it recognized as a disease entity when Bretonneau studied an epidemic in Tours and first described the intestinal lesions Louis in 1829 gave a description of the disease and the name 'Fievre Typhoide" To a group of Americans great credit is due for distinguishing typhoid fever from typhus fever W W Gerhard of Philadelphia a student of Louis had the opportunity of observing an

epidemic of typhoid and typhus fever and in 1837 published in the American Journal of Medical Sciences an article which clearly differentiates these diseases Credit is also due Alfred Stillé George Shattuck and James Jackson Senior and Junior for having further popularized the existing knowledge of this disease Budd in the years 1856 to 1860 published in the Lancet for the first time that the infective agent was in the stools In 1880 Eberth discovered the specific cause of the disease and in 1895 Widal brought the agglutination reaction of Pfeiffer into prominence as being of value in the diagnosis of typhoid

Incidence —The disease is universally distributed occurring in practically all parts of the world In former years it was a very prevalent infection during the summer and early autumn months in the most populated areas of the temperate climates Contaminated water and infected food are its chief sources Fingers food and flies frequently account for its local distribution in homes and hospitals During the past twenty five years there has been a marked decrease in the incidence and death rate of this disease In 1910 in 78 American cities with a total population of 22 573 435 the death rate was 20 54 per 100 000 In 1940 in the same cities with a total population of 35 895 038 the death rate had fallen to 0 48 per 100 000

Typhoid fever has been one of the greatest scourges of armies and during the Spanish American War among 107 973 men in the national encampments there were 20 738 cases of typhoid with 1580 deaths In the South African War in the British army of 557 653 there were 57 684 cases of typhoid with 8225 deaths During the World War the American army consisting of more than 4 000 000 men had only 227 deaths from typhoid fever This record is a great tribute to the efficiency of modern sanitary methods and of prophylactic immunization against the disease

Season —The maximum number of cases occurs in the autumn with a slight variability according to location A rise in the prevalence of the disease is noted in July extending through August and September and decreasing in October

Age —Typhoid fever is distinctly a disease of youth and early adult life occurring with greatest frequency between the ages of fifteen and thirty years It is rare in infancy and in the elderly Males and females are equally susceptible

Immunity —Not all persons exposed to the infection contract the disease After recovery a partial immunity develops but second attacks are not uncommon An acquired immunity can be produced in most persons by the subcutaneous injection of increasing doses of killed cultures of *E typhosa*

Bacteriology —The *Eberthella typhosa* is a short actively motile aerobic organism with rounded ends growing readily at body temperature in all culture media particularly well in milk which it does not coagulate It is a gram negative bacillus and does not ferment lactose or dextrose When grown on bismuth sulfite media the typhoid colony has a black metallic sheen whereas the colon bacillus colonies are white *Salmonella paratyphi* and *S schottmulleri* colonies have a green color The bacillus is killed when exposed to a temperature of 60° C for ten minutes it may live for months at a temperature below freezing The ordinary disinfectants such as carbolic acid 1 20 solution and bichloride of mercury 1 1000 solution are quite efficacious in killing the organism Park found that when *E typhosa* are dried the majority of them die within a few hours a few may survive for several weeks or months Direct sunlight kills most of them after exposure for several hours but they may live several days in water

Etiology —*Entrance to the Body* —The *E typhosa* gain entrance directly through the gastro intestinal tract Entering supposedly through Peyer s patches and the solitary lymph follicles they pass to the mesenteric lymph nodes and from this point through the thoracic duct into the blood stream After entering the blood they are distributed into every organ of the body During the first week of the disease the organisms are easily recovered from the blood and in a few patients they can be isolated from the urine and feces however as the disease advances the organisms usually disappear from the blood stream and are recovered in an increasing number of cases from the urine and stools The site of greatest multiplication of the bacilli is probably the biliary system since *E typhosa* are recovered in greater numbers from the duodenal contents and diminish in frequency as the lower intestinal tract is reached They

are eliminated from the body through the urine and feces Approximately 75 to 85 per cent of positive cultures are obtained from the blood during the first week of the infection From the second to the third week stool cultures are positive in a high percentage of cases As recovery takes place the organisms first disappear from the blood and later from the urine and feces

Modes of Infection—Every patient with typhoid fever should be regarded as a source of infection for the spread of the disease and since the organisms are easily destroyed by proper disinfection of the excreta it is necessary to adopt strict measures to prevent the spread in households hospitals and communities

Water—Infected water is by far the most common source of widespread epidemics Statistical studies made in this country have shown that this is a prevalent source of infection The steady decrease in the incidence of typhoid fever in communities where the water supply is improved is the best evidence that many cases are due to water borne infection

Food—Milk is the next most important source of infection many epidemics have been traced directly to this article of food Contamination of food may occur by washing utensils with infected water or by contact with flies previously contaminated with the excreta of typhoid patients but most frequently it is infected by contact with the hands of typhoid carriers All uncooked vegetables may be possible sources of infection butter and cheese are very rarely so Oysters and other shellfish may convey the disease if they live or are fattened in infected streams

Carriers—Every person recovering from typhoid fever should be considered a carrier until repeated stool and urine cultures fail to show *E typhosa* The organism may be present in the stools for months or years after the patient has completely recovered from the disease Occasionally perfectly healthy individuals who give no history of having had typhoid fever are found harboring the E typhosa bacillus About 80 per cent of the carriers are women Carriers who come in contact with food are particularly dangerous Typhoid Mary a cook was the first recognized typhoid carrier in the United States She caused at least ten out breaks of typhoid with at least fifty-one persons infected Recent study has shown the value of Vi aggglutination to determine carriers The Vi agglutinin apparently occurs only in those persons suffering with actual typhoid fever or who are harboring these organisms and can therefore be used as a successful screen test in the detection of carriers The use of sulfonamides in the treatment of carriers has not as yet proved of any lasting value

Pathologic Anatomy—The most characteristic changes to be observed in typhoid fever are found in the intestinal tract The Peyer s patches and solitary glands are the places where the typical changes are first seen they become red and swollen and project above the surface of the bowel The ordinary lymphoid tissue is replaced by an enormous number of large mononuclear phagocytes and there is almost a complete absence of polymorphonuclear leukocytes in these areas These large cells to which attention was particularly directed by Mallory are probably endothelial in origin and come from the reticulo endothelial system By the end of the first week or ten days due to engorgement of the vessels and perhaps pressure from the accumulation of endothelial cells the blood supply to Peyer s patches is interfered with and there begins on the surface of the swollen patch a superficial necrosis which as it progresses forms an ulcer The ulcers are usually round or slightly oval with the long axis corresponding to the long axis of the bowel Contiguous ulcers may coalesce especially near the ileocecal valve so that the lower ileum presents the picture of one large ulcerated area The cecum and proximal part of the colon are involved in about one third of the cases The size and number of ulcerations bear no relation to the severity of the disease indeed the ulceration is not a fundamental part of the pathology of typhoid fever—patients may die from the toxemia of the disease and at autopsy show very few or no lesions in the intestine Healing takes place without the formation of cicatricial tissue the ulcers being covered by a simple epithelium without glands The mesenteric lymph glands in the involved areas particularly those which drain the lower ileum are hy

peremic, sometimes quite soft, and frequently hemorrhagic The same changes are observed in the lymph nodes as in the Peyer's patches, namely, the engorgement of the sinuses by large mononuclear phagocytic cells similar to those seen in Peyer s patches Necrosis may take place with rupture of the gland into the peritoneal cavity

Spleen—As a rule the spleen is enlarged Sometimes its weight may reach 600 to 700 Gm which is three to four times that of a normal spleen It is soft and on microscopic examination shows an accumulation of large endothelial phagocytes Rupture may occur spontaneously or as a result of injury producing a peritonitis

Liver—There is usually cloudy swelling of the liver and also small areas of focal necrosis These necrotic areas may resemble small tubercles but on close examination they are found to be an accumulation of the large endothelial cells which have blocked sinusoids and caused necrosis MacCallum believes that the liver cells are not involved but are merely pushed aside by the phagocytes Since bile greatly enhances the growth of the typhoid bacillus the gall bladder is invariably infected Acute cholecystitis is not rare and occasionally typhoid ulcers have been found in the wall of the gallbladder

Kidneys—The kidneys show cloudy swelling the result of the action of toxins on these organs While there is usually a bacilluria cystitis and pyelitis are uncommon

Respiratory Organs—The lungs may be the seat of pneumonic consolidation which may be of either the bronchial or lobar variety This is usually secondary, very rarely does the *E typhosa* cause a pneumonia Bronchitis is a common early symptom Abscesses and gangrene may develop as well as infarcts

Muscles—There is usually a hyaline degeneration of muscles in which the fibers lose their transverse striation Those most commonly involved are the muscles of the thighs arms and diaphragm

Cardiovascular System—Endocarditis is quite rare though there have been cases reported in the literature Pericarditis due to the *E typhosa* is almost unheard of The most frequent change in the circulatory system is an extremely soft flabby myocardium in which many of the fibers have lost their striation Fatty degenerative changes in the arteries do occur but these are not specific for typhoid The lesions are usually located in the intima or media and it is possible that many of the sudden deaths in typhoid are the result of degenerative arterial changes Arterial thrombosis is rare but thrombophlebitis is quite common especially in the left femoral vein

Nervous System—Very few changes are made out Meningitis is rare, optic neuritis sometimes occurs Parenchymatous changes have been observed in the peripheral nerves even when there were no particular symptoms of neuritis

Symptomatology—The incubation period is quite variable and may last from five to forty days The average is from ten to fourteen days During this stage there are few or no symptoms although if careful observations are made the temperature might show a slight elevation in the evening The onset is rarely acute and it is with a great deal of difficulty that a patient can state a definite beginning Chills or chilly sensations alternating with hot flashes occur fairly frequently Headache, backache anorexia diarrhea epistaxis and constipation with generalized aching usually constitute the outstanding prodromal symptoms Bronchitis is frequent often it is quite misleading particularly when associated with a leukocytosis, which is not an infrequent observation It is usually a generalized condition that clears up within the first week or ten days of the disease

Fever—It is rare that an individual becomes infected with the *E typhosa* without having fever although during epidemics positive blood cultures are at times obtained from those who are in contact with the disease but who exhibit no clinical manifestations

The usual febrile response in typhoid is characterized for purposes of description by three phases first the rise second the period of continued fever third the fall During the first week of the infection there is a gradual daily increase in the height of the fever which rises in a steplike manner until at the end of a week or ten days it has reached a level of 103° or of 104° F The second phase is the period of continued fever

in which the daily remissions are very slight but which lasts for ten days to two weeks The third period, that of defervescence begins about the third week and lasts for seven to ten days in this period the daily fluctuations are most marked and resemble those of a septic infection

Not all patients with *Eberthella* infection run such a typical temperature curve and in those with quite severe infections the temperature may be quite irregular Sudden changes in the temperature unless caused by hydrotherapy or drugs should make one suspicious of complications After a large hemorrhage the fever may drop 6° or 8° F After perforation there may be an initial fall of fever followed by a rise During convalescence there is a tendency for the temperature to be subnormal

Pulse—The pulse in typhoid presents two characteristics—its relative slowness in comparison with the height of the temperature and the fact that it is dicrotic These characteristics are among the earliest and most suggestive aids in diagnosis A pulse rate of 80 to 90 with a temperature of 103° to 104° F is not uncommon Many patients have gone through typhoid fever with a pulse rate of less than 100 Dicrotism which is not as common in children as in adults may persist during the entire course of the disease and extend well into convalescence but as a rule it disappears during the third week A persistently rapid pulse early in the disease signifies a rather severe infection and marked toxemia

Skin—The rose colored rash which is usually described as typical of typhoid fever makes its appearance from the seventh to the tenth day It is observed most commonly upon the abdomen but may appear on the chest and back It consists of small round elevated rose colored areas from 2 to 4 mm in diameter that disappear on pressure This rash usually comes in crops and after persisting for two or three days it disappears occasionally leaving a brownish stain In some patients the eruption may be quite abundant and in the white race it is seen in approximately 90 per cent of the patients Herpes is extremely rare Sudamina occurs with considerable frequency Areas of superficial gangrene may develop particularly after the prolonged use of ice packs Swelling or edema of the skin occasionally occurs but most commonly as a result of thrombosis of a femoral vein Sometimes with the onset of nephritis edema is seen The occurrence of bed sores is quite rare and is usually due to negligence on the part of the nurse although in the days when typhoid patients received a very low caloric diet pressure over the sacrum was usually sufficient to produce acute decubitus ulcers in some patients

Nervous Manifestations—Headache of a very severe character is a fairly frequent initial symptom Pain is usually located in the frontal region most commonly bitemporal Sometimes this constitutes a very distressing symptom although as a rule the pain is of a dull uncomfortable continuous character Convulsions when they occur are most commonly observed in young children Delirium listlessness photophobia twitching of the muscles and somnolence are usually indications of a severe infection Sometimes the headache and stiffness of the neck would lead one to suspect meningitis

Gastro intestinal Tract — Occasionally nausea vomiting and diarrhea are observed sometimes there is marked abdominal distention associated with the diarrhea Such symptoms in the beginning of typhoid fever are usually brought about when very little attention is paid to dietary regulation or when a purgative is given at the onset of the illness The spleen is practically always enlarged except in individuals of the colored race It becomes palpable about the end of the first week of the disease but seldom extends over 3 cm below the costal border

Blood—As a rule there is a rather marked leukopenia in typhoid fever The average count will vary from 3000 to 5000 white blood cells per cubic millimeter The decrease in the number of leukocytes is accounted for by a diminution in the number of the neutrophilic cells As the disease advances there is a gradual decrease in the number of red cells and an equivalent decrease in the hemoglobin The systolic and diastolic blood pressures gradually fall during the course of the disease and in persons with a normal blood pressure this may amount to as much as 10 to 20 mm of mercury

Chills—Chills may occur at the onset of

the disease, and they may recur throughout the course of the disease without explanation However, they usually mark the onset of some complication, or follow the administration of an antipyretic Sometimes they are associated with constipation

Epistaxis is one of the early symptoms and occurs more frequently in typhoid fever than in any of the infectious diseases It may be profuse and serious and recur frequently during the course of the illness

Bronchitis is a frequent initial symptom and may be accompanied by a severe or distressing cough On physical examination there are many sibilant rales over the chest Pneumonia and atelectasis occasionally occur

Renal Symptoms—Albuminuria is a common finding particularly during the febrile stage This, as a rule is accompanied by the presence of a few casts As the temperature subsides and the toxemia diminishes the albuminuria gradually disappears *E typhosa* occur in the urine in approximately 40 per cent of patients Occasionally nephritis of the acute variety is observed Pyelitis may involve one or both kidneys occurring either in the early stages or during the height of the disease Perinephritic abscesses are rare

Relapse—This usually occurs after the patient has had a normal temperature for five to ten days As a rule it is a much milder infection and runs a shorter course than the original disease although occasionally it may be more severe Infrequently more than one relapse occurs The onset is usually without warning and is accompanied by the usual signs and symptoms of typhoid fever The rose spots reappear the spleen which was at one time palpable is easily felt again the temperature rises but is usually not as high as on the former occasion Relapse may last from one to three weeks The causes of relapse are purely speculative but they have been most commonly attributed to dietary indiscretion however proof for such a theory is lacking

Complications—Intestinal hemorrhage is one of the most serious complications The bleeding may vary in intensity from that which is detectable *only* by chemical means to an extensive massive hemorrhage which may completely exsanguinate the patient No relationship can be found to exist between the severity of the disease and the frequency or severity of intestinal hemorrhage Severe hemorrhage may occur in a very mild infection whereas a severe case may have no hemorrhages at all It is a serious complication and occurs usually in about 6 to 7 per cent of all cases it is most commonly observed during the third week of illness and comes as a rule without warning The first evidence of its occurrence may be a sudden drop in the temperature or a marked increase in the pulse rate accompanied by pallor chilliness sweating and anxiety on the part of the patient The bleeding is a result of the erosion of one of the small or medium sized arteries situated in Peyer s patches The occurrence of intestinal hemorrhage markedly increases the seriousness of the prognosis about 20 per cent of those who develop this complication succumb to the disease

Perforation—This is by far the most important the most dreaded and most fatal complication of typhoid fever In a great majority of instances it occurs during the third week in the severe cases particularly those associated with diarrhea, tympanites and hemorrhage The most common site of the perforation is the lower portion of the ileum As a rule the perforation occurs singly but there may be more than one opening in the intestine The actual cause is usually abdominal distention or the result of vomiting or straining at stool

By far the most important single symptom is a sudden sharp pain referred to the *lower right abdominal quadrant* sometimes it may be diffuse and detected only by deep pressure in the abdomen Shortly after the onset of pain a decided change is observed in the condition of the patient—there is nausea and vomiting the pulse increases in rate the temperature usually falls *to be* followed by a rise there is local rigidity of the abdominal muscles particularly near the site of perforation and after a short space of time the entire abdomen becomes markedly rigid Distention may or may not occur If gas escapes into the abdominal cavity the liver dulness becomes obliterated If there has been a leakage of fluid into the abdominal cavity it can be detected by the presence of a friction rub over the splenic or

hepatic areas or by the demonstration of shifting dulness in either flank With the perforation there is usually an increase in the leukocytes although this sign cannot always be relied upon as a *sine qua non* for the reason that unless the leukocyte count is known before the perforation occurs a slight rise cannot be appreciated However if several counts are made in the course of three or four hours it will be observed that there is a steady increase in the number of white cells It is difficult to distinguish between an acute cholecystitis acute appendicitis rupture of a mesenteric lymph node and intestinal perforation In a patient presenting symptoms of such a lesion it is much better to advise an exploratory laparotomy rather than delay too long for the development of a perfectly typical picture Even under the most favorable conditions the mortality is distressingly high

Cholecystitis—Acute cholecystitis is a rather rare complication of typhoid fever When we remember that the bile is a favorite medium for the growth of *E typhosa* it seems strange that the gallbladder is not involved more frequently in an inflammatory process Suppuration however may occur and when it does is similar to the symptoms which are observed in an acute cholecystitis from any other cause The *E typhosa* grows well in any medium that contains bile so that it is not unusual to find that the bile still contains this organism after complete recovery from typhoid fever

Thrombosis—This is usually a late complication of typhoid occurring in the majority of cases after the fourth week and frequently during convalescence The femoral vein on the left side is more frequently involved than any other This complication is ushered in usually with a chill increase in fever and pulse rate with soreness or pain over the involved vein The fever and pain usually increase for two or three days at the end of which time the involved blood vessel may be palpated as a very tender superficial cord Accompanying this there are usually swelling of the extremity an increase in the number of leukocytes but seldom any marked circulatory change in the limb A grave danger following thrombosis is a possible dislodgment of the clot causing pulmonary embolism and sudden death

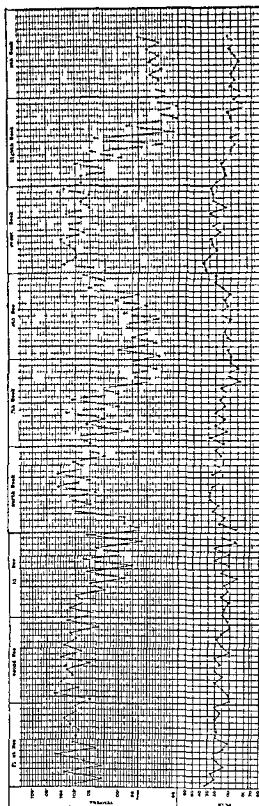

Fig 20—Temperature and pulse record of a twelve-year-old boy with typhoid fever The temperature began to drop at the end of the third week At the beginning of the fourth week he had a recrudescence At the end of the fifth week his temperature again came down but rose again during the sixth week, when he developed a relapse which lasted almost two weeks During the seventh week the blood culture was again positive for *E typhosa*.

Respiratory System—*Epistaxis* is quite common at the onset particularly in children

the disease and they may recur throughout the course of the disease without explanation However, they usually mark the onset of some complication or follow the administration of an antipyretic Sometimes they are associated with constipation

Epistaxis is one of the early symptoms and occurs more frequently in typhoid fever than in any of the infectious diseases It may be profuse and serious and recur frequently during the course of the illness

Bronchitis is a frequent initial symptom and may be accompanied by a severe or distressing cough On physical examination there are many sibilant rales over the chest Pneumonia and atelectasis occasionally occur

Renal Symptoms —Albuminuria is a common finding particularly during the febrile stage This as a rule is accompanied by the presence of a few casts As the temperature subsides and the toxemia diminishes the albuminuria gradually disappears *E typhosa* occur in the urine in approximately 40 per cent of patients Occasionally nephritis of the acute variety is observed Pyelitis may involve one or both kidneys occurring either in the early stages or during the height of the disease Perinephritic abscesses are rare

Relapse —This usually occurs after the patient has had a normal temperature for five to ten days As a rule it is a much milder infection and runs a shorter course than the original disease although occasionally it may be more severe Infrequently more than one relapse occurs The onset is usually without warning and is accompanied by the usual signs and symptoms of typhoid fever The rose spots reappear the spleen which was at one time palpable is easily felt again the temperature rises but is usually not as high as on the former occasion Relapse may last from one to three weeks The causes of relapse are purely speculative but they have been most commonly attributed to dietary indiscretion however proof for such a theory is lacking

Complications —Intestinal hemorrhage is one of the most serious complications The bleeding may vary in intensity from that which is detectable only by chemical means to an extensive massive hemorrhage which may completely exsanguinate the patient No relationship can be found to exist between the severity of the disease and the frequency or severity of intestinal hemorrhage Severe hemorrhage may occur in a very mild infection whereas a severe case may have no hemorrhages at all It is a serious complication and occurs usually in about 6 to 7 per cent of all cases it is most commonly observed during the third week of illness and comes as a rule without warning The first evidence of its occurrence may be a sudden drop in the temperature or a marked increase in the pulse rate accompanied by pallor chilliness sweating and anxiety on the part of the patient The bleeding is a result of the erosion of one of the small or medium sized arteries situated in Peyer s patches The occurrence of intestinal hemorrhage markedly increases the seriousness of the prognosis about 20 per cent of those who develop this complication succumb to the disease

Perforation —This is by far the most important the most dreaded and most fatal complication of typhoid fever In a great majority of instances it occurs during the third week in the severe cases particularly those associated with diarrhea tympanites and hemorrhage The most common site of the perforation is the lower portion of the ileum As a rule the perforation occurs singly but there may be more than one opening in the intestine The actual cause is usually abdominal distention or the result of vomiting or straining at stool

By far the most important single symptom is a sudden sharp pain referred to the lower right abdominal quadrant sometimes it may be diffuse and detected only by deep pressure in the abdomen Shortly after the onset of pain a decided change is observed in the condition of the patient—there is nausea and vomiting the pulse increases in rate the temperature usually falls to be followed by a rise there is local rigidity of the abdominal muscles particularly near the site of perforation and after a short space of time the entire abdomen becomes markedly rigid Distention may or may not occur If gas escapes into the abdominal cavity the liver dulness becomes obliterated If there has been a leakage of fluid into the abdominal cavity it can be detected by the presence of a friction rub over the splenic or

or premature labor in approximately 60 per cent of the patients

Diagnosis —The diagnosis of typhoid fever may be one of the easiest or one of the most difficult problems which a physician encounters The clinical findings are of greatest significance the history of gradual onset with malaise epistaxis headache drowsiness bronchitis increasing temperature from day to day a slow pulse dicrotic in character roseolar skin eruption and an enlarged spleen is quite suggestive If these symptoms can be connected with a recent trip to a known typhoid area they become of greater importance A leukopenia is of considerable significance although it does occur in other diseases

Blood Culture —A culture from the blood should be made from every suspected case in which there is continued fever During the first week of the disease the *Eberthella* organism can be recovered in approximately 85 per cent of the patients As the disease advances positive results become less frequent

Cultures from Urine and Feces —During the first week of the illness positive cultures may be obtained in approximately 10 per cent of patients as the disease progresses the organism is obtained with greater frequency by the end of the third week 80 per cent of typhoid patients yield positive cultures in the excreta

Widal Reaction —When blood cultures cannot be made the Widal test is of considerable importance for it is positive in some stage of the disease in practically all cases This reaction is based on the presence of specific agglutinins for the *E typhosa* in the patient s blood and was first utilized by Widal as a method of diagnosing typhoid fever This reaction is usually not positive until the second week and in some cases several tests must be done before a positive result is obtained Agglutination with a dilution of the patient s serum in a strength of 1 50 or 1 100 is considered positive Widespread use of prophylactic injections of typhoid vaccine has lessened to some extent the diagnostic value of this test If the reaction continues to be positive with a rising dilution of serum it is of considerable importance in making the diagnosis

Differential Diagnosis —Many diseases may simulate typhoid fever so that it will not always be possible to make a positive diagnosis within the first five or six days of the infection Keeping in mind the general clinical picture of the disease with help afforded by blood urine and stool cultures and the Widal reaction it is generally possible to make a positive diagnosis The diseases most frequently giving difficulty are

Malaria —At times malaria particularly the estivo autumnal type may be confused with typhoid fever In malaria the daily fluctuation of the temperature is more marked chills occur with greater frequency and irregularity The spleen is usually larger and firmer and the parasites can usually be demonstrated in the blood On occasions it may be necessary to give at least 30 grains of quinine a day for three or four days as a therapeutic test Atabrine may be used for the therapeutic tests instead of quinine giving 1½ grains (0 1 Gm) three times a day for three days

Miliary Tuberculosis —In this disease, especially when there are no localizing symptoms the differentiation from typhoid fever may be extremely difficult Both have an insidious onset both may be characterized by prolonged fever bronchitis malaise anorexia gastro intestinal symptoms and a positive Widal reaction A familial history of tuberculosis is of help The pulse and temperature ratio so commonly seen in typhoid fever are not observed in this form of tuberculosis The pulse rate is faster seldom dicrotic the respirations are increased and the temperature curve is much more irregular than in typhoid While leukopenia may be present a slight leukocytosis is more common In miliary tuberculosis there is cyanosis of the lips and fingertips coughing and localized signs in the lungs or in the central nervous system An x ray examination of the chest together with serologic studies of the blood and culture from the stools will help greatly in the differentiation

Bacterial endocarditis is usually distinguished with ease although in some cases considerable difficulty may exist. The fever in this condition is seldom so continuous or so high as in typhoid Frequent and irregular chills with a septic type of temperature are much more common The presence of petechiae in the conjunctivae is of much impor

and young adults *Bronchitis* is frequently seen in the early stages of the disease and in the majority of cases is characterized by severe coughing *Catarrhal laryngitis* is occasionally seen and may be associated with extensive ulceration the ulcerative lesions sometimes developing so slowly that they escape recognition until edema occurs Unusual hoarseness tickling sensation in the throat and loss of voice should be symptoms which warn of the development of this condition *Pleurisy* is rather rare in typhoid fever but it may occur at any period of the disease as a primary condition or secondary to some other lesion such as pneumonia or infarction It is usually fibrinous but in a few instances it may become purulent *Lobar pneumonia* is infrequent It is usually caused by the pneumococcus although the *E typhosa* occasionally may be the causative agent *Bronchopneumonia* occasionally develops during the course of the disease, it usually occurs in delirious patients and is sometimes brought on by aspiration of foreign material *Infarction of the lung* may occur as a result of the dislodgment of a thrombus from the femoral vein

Circulatory Complications —Degenerative changes in the heart muscle are fairly common These usually involve the musculature in the form of a parenchymatous degeneration of the fibers Evidence of the existence of such conditions is manifested usually by an increased rate in the pulse lowering of the blood pressure irregularity of the heart and diminution in the intensity of the first heart sound which may be accompanied by a soft systolic murmur Endocarditis and pericarditis are very rare

Nervous System —In a great number of cases headache disturbed sleep delirium particularly at night and tremors—*subsultus tendinum*—are the conditions most frequently observed Stiffness of the neck and suggestive symptoms of meningitis are occasionally observed True purulent inflammation of the meninges is rare Psychoses are sometimes encountered They may appear at any stage of the disease and vary from the manic depressive type to melancholia or mild states of confusion which usually are not serious and disappear during convalescence *Peripheral neuritis* involving the nerves of the lower extremities is fairly common The tender toes' described by Osler are occasionally seen Polyneuritis may occur Convulsions are rare and most commonly observed in children usually at the onset of the disease They may be due to inflammation of the brain or to a marked toxemia

Genito-urinary System —In severe cases with marked toxemia and stupor, retention of the urine is sometimes seen In some patients there may be incontinence without retention Slight albuminuria with a few tubular casts is nearly always noted but actual nephritis is uncommon In nearly all fatal cases there is cloudy swelling with degeneration of the cells of the convoluted tubules of the kidneys Hemorrhagic nephritis is quite rare recovery from the milder irritations of the kidney is the rule *Eberthella* bacilluria is present in 40 per cent of the cases and may persist for many months Cystitis and pyelitis may occur either as a result of infection by the *E typhosa* or from a pyogenic organism Gangrene of the bladder has been observed Orchitis is a rare complication which may occur during convalescence It usually terminates in resolution although at times suppuration takes place

Lesions of the Bones —Periostitis osteitis and osteomyelitis are not uncommon complications They may occur even months after recovery from typhoid fever The tibiae femur, ribs bones of the forearm and clavicle are most often affected Arthritis is occasionally observed it may be monarticular or polyarticular The hip joint is occasionally involved and is sometimes the site of spontaneous dislocation In the absence of suppuration complete recovery with good function is the rule The condition known as typhoid spine depends for its production on an inflammatory lesion involving the periosteum of the bony structure of the spine usually in the lumbar region Sometimes the intervertebral disks are affected It is usually accompanied by pain on motion and tenderness over the spine

Other complications such as parotitis are rare This is usually due to lack of proper nursing care and comes from a mouth which has not had the usual hygienic treatment

Pregnancy associated with typhoid fever is unfavorably affected resulting in abortion

or premature labor in approximately 60 per cent of the patients

Diagnosis—The diagnosis of typhoid fever may be one of the easiest or one of the most difficult problems which a physician encounters The clinical findings are of greatest significance the history of gradual onset with malaise epistaxis headache drowsiness bronchitis increasing temperature from day to day a slow pulse dicrotic in character roseolar skin eruption and an enlarged spleen is quite suggestive If these symptoms can be connected with a recent trip to a known typhoid area they become of greater importance A leukopenia is of considerable significance although it does occur in other diseases

Blood Culture—A culture from the blood should be made from every suspected case in which there is continued fever During the first week of the disease the *Eberthella* organism can be recovered in approximately 85 per cent of the patients As the disease advances positive results become less frequent

Cultures from Urine and Feces—During the first week of the illness positive cultures may be obtained in approximately 10 per cent of patients as the disease progresses the organism is obtained with greater frequency by the end of the third week 80 per cent of typhoid patients yield positive cultures in the excreta

Widal Reaction—When blood cultures cannot be made the Widal test is of considerable importance for it is positive in some stage of the disease in practically all cases This reaction is based on the presence of specific agglutinins for the *E typhosa* in the patient s blood and was first utilized by Widal as a method of diagnosing typhoid fever This reaction is usually not positive until the second week and in some cases several tests must be done before a positive result is obtained Agglutination with a dilution of the patient s serum in a strength of 1 50 or 1 100 is considered positive Widespread use of prophylactic injections of typhoid vaccine has lessened to some extent the diagnostic value of this test If the reaction continues to be positive with a rising dilution of serum it is of considerable importance in making the diagnosis

Differential Diagnosis—Many diseases may simulate typhoid fever so that it will not always be possible to make a positive diagnosis within the first five or six days of the infection Keeping in mind the general clinical picture of the disease with help afforded by blood urine and stool cultures and the Widal reaction it is generally possible to make a positive diagnosis The diseases most frequently giving difficulty are

Malaria—At times malaria particularly the estivo autumnal type, may be confused with typhoid fever In malaria the daily fluctuation of the temperature is more marked chills occur with greater frequency and irregularity The spleen is usually larger and firmer and the parasites can usually be demonstrated in the blood On occasions it may be necessary to give at least 30 grains of quinine a day for three or four days as a therapeutic test Atabrine may be used for the therapeutic tests instead of quinine giving 1½ grains (0 1 Gm) three times a day for three days

Miliary Tuberculosis—In this disease, especially when there are no localizing symptoms the differentiation from typhoid fever may be extremely difficult Both have an insidious onset both may be characterized by prolonged fever bronchitis malaise anorexia gastro intestinal symptoms and a positive Widal reaction A familial history of tuberculosis is of help The pulse and temperature ratio so commonly seen in typhoid fever are not observed in this form of tuberculosis The pulse rate is faster seldom dicrotic the respirations are increased and the temperature curve is much more irregular than in typhoid While leukopenia may be present a slight leukocytosis is more common In miliary tuberculosis there is cyanosis of the lips and fingertips coughing and localized signs in the lungs or in the central nervous system An x ray examination of the chest together with serologic studies of the blood and culture from the stools will help greatly in the differentiation

Bacterial endocarditis is usually distinguished with ease although in some cases considerable difficulty may exist The fever in this condition is seldom so continuous or so high as in typhoid Frequent and irregular chills with a septic type of temperature are much more common The presence of petechiae in the conjunctivae is of much impor

tance and significance Dyspnea, and the presence of a heart murmur, which increases in intensity, joint pains and red cells in the urine are of differential value Infarcts occur commonly in endocarditis The blood culture usually furnishes the conclusive evidence needed to confirm the diagnosis

Pyelitis with high fever although usually not of the continuous type may last from two to three weeks without localizing symptoms and may thus cause confusion A leukocytosis tenderness in the back or over the kidney, together with the presence of pus in the urine serve to establish a diagnosis

Typhus Fever —Formerly these two diseases were frequently confused and even now sporadic cases will sometimes give difficulty As a rule the onset of typhus is rapid and dramatic often with a chill and intense, persistent headache the fever rises rapidly and remains high without remissions, the leukocyte count is elevated, the spleen when enlarged becomes so earlier than in typhoid fever The characteristic rash appears usually on the fifth to sixth day and its extent depends on the severity of the disease The lesions are maculopapular and slightly oval and a few may coalesce They do not fade with pressure and very frequently they have a hemorrhagic center Typhus lasts as a rule two to two and one half weeks and frequently ends abruptly with a crisis Serologic tests for typhoid are negative but in typhus fever there is usually a positive Felix Weil reaction at the end of ten days

Trichinosis —In cases of trichinosis in which there is prostration high fever diarrhea and a rash simulating the rose spots of typhoid, diagnosis may be confusing at the onset As a rule the muscular soreness of trichinosis is much more severe than that in typhoid and is greatly aggravated by motion The blood count usually reveals a leukocytosis and the differential count will show a marked eosinophilia Skin sensitization tests for the *Trichina spiralis* can be tried in doubtful cases

Meningitis —With the sudden onset of typhoid with marked delirium headache and stiffness of the neck there may be present all the signs of acute meningitis including opisthotonos and twitching of the muscles A lumbar puncture and study of the spinal fluid will quickly establish the diagnosis

Syphilitic Fever —In latent syphilis there may occur a long continued fever with constitutional symptoms but with *few or no* manifestations of syphilis The history of a primary lesion, a positive Wassermann and negative serologic tests for typhoid are of value in differentiating the two conditions Sometimes a therapeutic test may be of value

Undulant Fever —Acute infections with the *Brucella* group of bacteria can be differentiated only by recovery of the organism from the blood stream or an increasing titer of agglutinins occurring in the patient's blood

Hodgkin's disease without adenopathy and *osteomyelitis* without localized signs may offer some difficulty A careful history physical examination, and blood counts will be of great help

Prognosis —*The Death Rate* —Deaths from typhoid fever vary considerably from year to year depending in a great measure upon the virulence of the infection Speaking generally the prognosis in the average case is very good The chances for recovery are much better in private practice than in general hospitals This in part, is due to the fact that in private patients the disease is detected earlier and treatment is instituted before the patient becomes seriously ill The average mortality among private patients is about 7 per cent whereas in general hospitals the average rate is approximately 14 per cent It is commonly believed that the general physical condition of the patient before the onset of the disease plays some part in determining the prognosis The mortality is high in infants in people over fifty and in the obese As a rule the most frequent cause of death is toxemia which is evidenced by unusually high fever restlessness delirium and abdominal *distention* Hemorrhage and perforation of course greatly increase the hazard Sudden death sometimes occurs without a reasonable explanation for such a catastrophe It is thought that marked toxemia affecting the heart muscle and causing ventricular fibrillation is the explanation

Prophylactic Measures —It is reasonable to assume that if all *E typhosa* were destroyed as they leave the body the disease

would soon be completely eradicated This problem, however is an extremely difficult one and is the chief cause of the spread of the disease from individual to individual or from an individual by contamination of water or food supplies to communities Hope for the complete eradication of typhoid lies in two directions (1) the early recognition of all patients with typhoid fever, (2) the establishment of rigid measures for the isolation of the patient and the complete destruction of all *E typhosa* from the body

Isolation and the Patient —An individual with typhoid fever need not necessarily be completely isolated provided certain restrictions regarding personal contact and disposal of excreta are strictly observed The screening of a well ventilated room to prevent the entrance of flies is most important After recovering from the disease stool examinations should be made in order to be certain that the patient no longer harbors the *E typhosa*

Disinfection of Stools and Urine —All excreta from the patient particularly the stools and the urine should be promptly disinfected Boiling or treatment with live steam is most efficacious Should this not be feasible the stools and the urine should be deposited in a receptacle to which is added 5 per cent carbolic acid solution or a 10 per cent solution of formaldehyde or perhaps a goodly quantity of quicklime The excreta should be allowed to remain in contact with these disinfectants for two or three hours If the attendant is made to realize that each specimen of stool and urine is a possible source of infection for spreading typhoid fever greater care will be exercised in their complete disinfection

Attendants —All individuals who administer to the typhoid patient should see that after performing any service the hands are washed in a solution of alcohol or cyanide of mercury The bed linen and the clothing worn by each patient should be soaked in a solution of carbolic acid or formaldehyde or be boiled before being sent to the laundry All dishes glasses and utensils that come in contact with the patient during the process of feeding must be properly sterilized by boiling after use Particular attention should be paid to the disinfection of bed pans and urinals

Food and Water —As previously stated the incidence of typhoid fever in a community is a good index of the intelligence of the local health officer A good clean fresh water supply must always be at hand Boiling water or the addition of 15 grains of fresh calcium hypochlorite to 36 gallons of water is sufficient to prevent infection Milk should be carefully protected from flies and dairies should be frequently inspected Milkers or those who handle milk must be known to be free from typhoid infection The pasteurization of milk renders this article of food safe for consumption

Prophylactic Vaccination —Protective vaccination against typhoid fever has amply demonstrated its value as is evidenced by the results obtained in the United States Army during the World War and the more recent report of Col G F Lull in the C C C Camps where 1 400 000 young men received the inoculations and only 237 developed typhoid fever of these 33 had not completed the series of inoculations The vaccine recommended for preventive inoculations contains 1 billion killed *E typhosa* 750 million killed *Salmonella paratyphi* and *S schottmulleri* per cubic centimeter Recent investigation has shown that infection with *Salmonella hirschfeldii* occurs occasionally in this country and is common in South America It therefore seems advisable to use the vaccine containing all four of the organisms to give the widest protection The subcutaneous administration of the vaccine in three doses of 0.5 cc 1 0 cc and 1 0 cc at weekly intervals has been the method used in the past With this method there is occasionally a systemic reaction It is particularly important to be sure that none is given intravenously Recent work by Tuft has shown the effects of the intracutaneous method of typhoid immunization with the complete elimination of annoying reactions The suggested dosage is 0 1 cc 0 15 cc and 0 2 cc of the ordinary combined vaccine given intracutaneously at weekly intervals The use of oral vaccine has not as yet proved of particular value in producing any appreciable immunity and until more satisfactory results have been demonstrated should not be utilized

Siler and Dunham using the mouse protection test for estimating the immunity fur-

nished by typhoid vaccination conclude that a large proportion of immunized persons are protected for a period of two or three years after vaccination They also observed that, using the same method of determining immunity in persons previously immunized the intracutaneous injection of 0 1 cc of typhoid vaccine produces an immunologic response equivalent to that obtained by the previous 3 subcutaneous injections The local and systemic reaction following the intracutaneous injection is relatively mild By employing this method or the subcutaneous injection of 0 5 cc of typhoid vaccine each year individual immunity can be kept at its height During an epidemic or in any household where typhoid fever develops, all exposed individuals should receive prophylactic inoculations

Treatment —In no disease is it more important to have the services of a skilled attendant or nurse than in typhoid fever Fortunately in the past twenty five years the profession has learned that good nursing care is of greater importance than drugs in the treatment of this disease If possible all patients with typhoid should be hospitalized When this is not feasible the patient should be placed in a clean well ventilated room, which has been stripped of its unnecessary furnishings and properly screened Should the services of a nurse not be available then some responsible member of the family should be given the necessary instructions concerning the care of the patient This should consist first and foremost in training and demonstrating how to disinfect thoroughly all excreta bedclothes dishes and anything else which might be contaminated All members of the family should be inoculated During the progress of the disease the nurse should be informed of the complications that may arise and should be instructed to report at once to the physician any unusual happening such as severe abdominal pain tarry or bloody stools a sudden rise or sudden drop in fever or any marked change in the pulse rate

The patient should be in a bed which is properly protected by sheeting to prevent soiling and contamination of the mattress From the outset a regular regime should be instituted and followed Particular attention should be paid to the teeth and the mouth should be kept clean Purgatives of all kinds are to be avoided especially after the first week of the disease A daily bath is not only necessary but it affords ample opportunity for a careful inspection of the patient *Alcohol rubs* are of great value and can be given three or four times daily They are of assistance in keeping the skin in good condition As a rule visitors do much more harm than good If admitted they should be present for only a short time

Diet—In the past patients with typhoid fever have suffered greatly from undernutrition and avitaminosis because of the popular belief that typhoid patients should receive only certain types of food The diets formerly prescribed were extremely limited and poor in caloric value Since the demonstration by Coleman and Shaffer that a patient can go through typhoid fever without marked loss of weight the restrictions previously imposed have been removed and it is now possible to feed the typhoid patient enough food to prevent the usual loss of weight It is definitely established that with a high caloric diet the mortality rate has been lowered and convalescence has been greatly shortened It is also believed that complications are less frequent than they were under former methods of treatment although relapses are perhaps slightly increased Carbohydrate being the food most easily digested should form a major portion of the diet Protein however is given in adequate amounts at least 1 Gm per kilo of body weight and fats are added in sufficient quantity to supply the caloric need The average patient with typhoid fever should receive from 3000 to 4000 calories per day depending in some measure upon his size and weight Since this diet must consist of liquids semisolids and soft foods it will be necessary to increase the carbohydrate beyond the usual intake of the average person Sugar must be used for this purpose and since milk sugar furnishes a sufficient caloric value without being too sweet it is used to increase the carbohydrate content of most diets Protein is given in the form of milk and eggs and curd Fats are supplied in butter and cream The chief articles of diet in typhoid fever are milk cream well cooked cereals such as rice grits cream of wheat strained oatmeal etc soft boiled

soft poached hard boiled or soft scrambled eggs toast or crackers fruit juices, stewed apples peaches or apricots apple float, butter, soups thickened with rice or barley flour creamed soups mashed or baked potatoes scraped meats or finely minced meat Simple desserts such as boiled custard, ice cream bread or tapioca pudding junket, cup custard blanc mange eggnog and jellies are allowed

From this list an ingenious nurse can prepare many combinations using various flavorings to keep the patient from tiring of any one food Lactose can be used in considerable amounts for sweetening The patient s food should be watched for its vitamin and mineral content Should the diet be low in either or both the deficiency should be corrected either by a rearrangement of the diet or supplying the deficiency from other sources When possible the patient should receive some foods which require mastication such as toast or crackers The type and quantity of food should be chosen for each individual patient No set formula should be followed other than to see that sufficient calories are taken One should never lose sight of the fact that one is treating a patient as well as a disease and due allowances must be made for the likes and dislikes of the individual

Hydrotherapy—The use of the cold tub bath as advocated by Brand has of late years been supplanted by sponge baths for the reduction of temperature and the improvement of the patient s well being A sponge bath correctly given is quite as efficacious as the tub In this type of hydrotherapy the patient is not moved from the bed A large rubber sheet is placed beneath him and by supporting the sides and ends of the rubber sheet it can be so designed as to form a shallow tub containing a sufficient amount of water to accomplish the necessary results A less extensive bath can be given in which the patient is sponged with water at a temperature of from 65° to 70° F Alcohol can be added to this if desired During the giving of any kind of bath friction of the patient s skin is of great importance in accomplishing the desired result The advantage of frequent bathing is that it quiets the nervous patient protects the skin reduces temperature and gives a sensation of well being and relaxation to the patient The baths should be given every four hours if the temperature is 102.2° F or over An ice cap to the head is usually most agreeable and ice caps to the abdomen are quite efficacious in reducing fever and in relieving a tendency to meteorism

Bowels—The ill effects of purgation in typhoid fever have long been known so that now no one would think of giving drugs to cause a daily evacuation At times mineral oil may be given if there is a tendency to fecal impaction Usually a daily enema of either normal salt solution or soap suds is quite sufficient

Treatment of Special Symptoms —*Toxemia*—For severe toxemia, fluids should be given very freely by mouth if possible, otherwise by hypodermoclysis Every typhoid patient should receive at least 3 liters of fluid within twenty four hours Hydrotherapy should be practiced regularly whether the temperature is high or not Headaches are usually controlled by the application of an ice bag or cold compresses Particular attention should be given to every patient who is delirious since in their delirium they may get out of bed or do themselves some injury

Tympanites and Diarrhea.—Meteorism like diarrhea is usually due to dietary indiscretions and can be controlled by further regulation of the food The majority of patients with marked distention are quite toxic Diarrhea in the majority of instances is due either to an excessive amount of fat in the diet or to the inability of the individual to digest properly the amount of food given The diarrhea can usually be controlled by eliminating fat and fruits from the diet and by administering bismuth subcarbonate in doses of 30 to 60 grains every three to four hours Opiates should not be given if they can be avoided

Hemorrhage—Hemorrhage from the bowel may vary considerably in amount The appearance of even a small amount of blood in the stool of a patient with typhoid fever is a warning for the physician to be on his guard All bleeding should be looked upon as a critical sign and should be so treated until proved otherwise In the event hemorrhage occurs all food by mouth should be stopped Small pieces of ice are given and

nished by typhoid vaccination conclude that a large proportion of immunized persons are protected for a period of two or three years after vaccination They also observed that, using the same method of determining immunity in persons previously immunized, the intracutaneous injection of 0 1 cc of typhoid vaccine produces an immunologic response equivalent to that obtained by the previous 3 subcutaneous injections The local and systemic reaction following the intracutaneous injection is relatively mild By employing this method or the subcutaneous injection of 0 5 cc of typhoid vaccine each year individual immunity can be kept at its height During an epidemic or in any household where typhoid fever develops, all exposed individuals should receive prophylactic inoculations

Treatment —In no disease is it more important to have the services of a skilled attendant or nurse than in typhoid fever Fortunately in the past twenty five years the profession has learned that good nursing care is of greater importance than drugs in the treatment of this disease If possible all patients with typhoid should be hospitalized When this is not feasible the patient should be placed in a clean well ventilated room, which has been stripped of its unnecessary furnishings and properly screened Should the services of a nurse not be available then some responsible member of the family should be given the necessary instructions concerning the care of the patient This should consist first and foremost in training and demonstrating how to disinfect thoroughly all excreta bedclothes dishes and anything else which might be contaminated All members of the family should be inoculated During the progress of the disease the nurse should be informed of the complications that may arise and should be instructed to report at once to the physician any unusual happening such as severe abdominal pain tarry or bloody stools, a sudden rise or sudden drop in fever or any marked change in the pulse rate

The patient should be in a bed which is properly protected by sheeting to prevent soiling and contamination of the mattress From the outset a regular regime should be instituted and followed Particular attention should be paid to the teeth and the mouth should be kept clean Purgatives of all kinds are to be avoided especially after the first week of the disease A daily bath is not only necessary but it affords ample opportunity for a careful inspection of the patient Alcohol rubs are of great value and can be given three or four times daily They are of assistance in keeping the skin in good condition As a rule visitors do much more harm than good If admitted they should be present for only a short time

Diet —In the past patients with typhoid fever have suffered greatly from undernutrition and avitaminosis because of the popular belief that typhoid patients should receive only certain types of food The diets formerly prescribed were extremely limited and poor in caloric value Since the demonstration by Coleman and Shaffer that a patient can go through typhoid fever without marked loss of weight the restrictions previously imposed have been removed and it is now possible to feed the typhoid patient enough food to prevent the usual loss of weight It is definitely established that with a high caloric diet the mortality rate has been lowered and convalescence has been greatly shortened It is also believed that complications are less frequent than they were under former methods of treatment although relapses are perhaps slightly increased Carbohydrate being the food most easily digested should form a major portion of the diet Protein however is given in adequate amounts at least 1 Gm per kilo of body weight and fats are added in sufficient quantity to supply the caloric need The average patient with typhoid fever should receive from 3000 to 4000 calories per day depending in some measure upon his size and weight Since this diet must consist of liquids semisolids and soft foods it will be necessary to increase the carbohydrate beyond the usual intake of the average person Sugar must be used for this purpose and since milk sugar furnishes a sufficient caloric value without being too sweet it is used to increase the carbohydrate content of most diets Protein is given in the form of milk and eggs and curd Fats are supplied in butter and cream The chief articles of diet in typhoid fever are milk cream well cooked cereals such as rice grits cream of wheat strained oatmeal etc soft boiled

a most perplexing problem The infection is usually in the gallbladder for which cholecystectomy has been performed The patient should be told of the existing condition taught how to take care of himself and not allowed to handle food for others

PARATYPHOID FEVER

Definition—Paratyphoid fever is an acute generalized infection which closely resembles both clinically and pathologically infection with *Eberthella typhosa* It is caused by the paratyphoid bacillus A or B According to the new terminology paratyphoid bacillus A is now known as *Salmonella paratyphi* and paratyphoid bacillus B as *Salmonella schottmulleri*

Etiology—No marked differences have been discovered between infection with paratyphoid bacillus A and paratyphoid B Epidemics of typhoid and paratyphoid may exist at the same time with one predominating over the other as was observed in various localities during the World War Immunization with *E typhosa* does not protect against infection with either *S paratyphi* or *schottmulleri* Since the human body is believed to be the normal habitat of the *E typhosa* it is equally true that it is also the normal habitat of the *Salmonella* organisms The method of transmission is similar to that previously described under Typhoid Fever

Bacteriology—The *S paratyphi* and *schottmülleri* are intermediaries between the *E typhosa* and the colon bacilli In 1896 Achard and Bensaude first recognized and described *S schottmülleri* The organism was isolated from the blood in 1898 by Gwyn In 1903 Paladino Blandino isolated *S paratyphi* from water This organism is more closely related to the *E typhosa* than *S schottmülleri* the latter resembling *B enteritidis* which is a common cause of poisoning by spoiled meat

Cultural Qualities—Both organisms grow on ordinary culture media where they are distinguished with some difficulty from *E typhosa* On bismuth sulfite media the *Salmonella* group of organisms produces colonies with a greenish color in contrast to the black colonies of the *E typhosa* The *Salmonella* organisms ferment glucose levulose and maltose much more than does the *E typhosa S paratyphi* forms acid in milk whereas the *S schottmulleri* forms alkali Agglutination tests are usually necessary to distinguish them from the *E typhosa*

Morbid Anatomy—Pathologic findings in typhoid vary but little from those of paratyphoid fever As a general rule the intestinal lesions of paratyphoid fever are more in the nature of a superficial necrosis of the lymphoid structures than like the deep ulcerations of typhoid Hemorrhage and perforation are not so common

Symptoms—As a rule the incubation period is slightly shorter than that of typhoid and the onset is much more abrupt Frequently there is a chill and the headaches are more intense however upon clinical grounds it is impossible to differentiate these infections from ordinary typhoid fever This is made possible only by laboratory examinations Paratyphoid as a rule is a milder infection and of shorter duration diarrhea is usually present and there are frequent sweats Relapses and recrudescences are about as common as in typhoid The typical roseola seen in typhoid fever occurs in paratyphoid Sometimes the onset may be with nausea vomiting abdominal pain and marked diarrhea which is frequently mistaken for food poisoning Occasionally one or more joints are involved in this infection a picture resembling that of acute rheumatic fever

Complications—These are similar to the ones previously pointed out as occurring in

the lips are moistened frequently with a mixture of lemon juice glycerin and water Absolute quiet is necessary An ice cap is placed on the abdomen with sufficient protection to prevent the skin from becoming too cold It is customary to give by hypodermic 100 units of parathyroid extract since this is of value in helping to increase the coagulability of the blood Calcium gluconate in 1 Gm doses intravenously is thought to be of value Morphine should be withheld unless there is marked restlessness anxiety and evidence of peripheral vascular collapse Transfusions of salt solution with glucose or whole blood should be given if indicated It is commonly believed that giving large quantities of fluid increases the tendency to hemorrhage by increasing the blood pressure but observation has not confirmed this suspicion Food is usually withheld for at least twenty four hours or until all evidence of bleeding has ceased

Perforation—The only treatment of any value for this condition is immediate surgical intervention Delay increases the mortality and robs the patient of his only chance of recovery It is much better to have an exploratory operation on a doubtful diagnosis than to wait too long for positive symptoms to appear Under the most favorable conditions the mortality is unusually high—50 to 60 per cent

Cholecystitis seldom requires surgical intervention Usually local applications of either hot or cold packs can be used to tide over an attack however the patient should be carefully watched and with increase in pain and a rising leukocyte count operation is indicated

Heart Failure—The use of sponge baths and an increased fluid intake have done much to prevent the development of myocardial weakness in typhoid fever A patient with this disease should be kept absolutely quiet with medication according to his needs

Phlebitis occasionally occurs The extremity involved should be kept warm at rest and elevated Sometimes the application of an ice bag over the involved vein affords comfort

Bed sores should not occur in this disease They usually result from inadequate attention Should they appear the patient should be put on a rubber ring turned on his side all pressure removed and healing applications applied

Drugs—In typhoid fever very few drugs are of any value In treating some of the complications they may be of definite value. Treatment of bacilluria with hexamethylenamine mandelic acid or with sulfanilamide is of value The use of various sulfonamide drugs in the treatment of typhoid fever has been very disappointing Seemingly it has no beneficial action on the progress of the disease although it is of value in treating the cystitis which accompanies the infection Ill effects may follow the administration of these remedies particularly the effect on the blood forming organs Codeine for headaches mineral oil for constipation phenobarbital for restlessness are all useful

Vaccine and Serum Treatment—The treatment of typhoid fever with typhoid vaccine has been tried by many observers but results from a large series of cases have not substantiated the claims for this form of therapy When given at all the dosage must be quite small in comparison with the doses used for the prevention of the disease The remedy has been administered both subcutaneously and intravenously The initial intravenous dose should not be over 10 000 000 organisms the subcutaneous dose less than 500 000 000 Between injections there should be an interval of several days Recent reports concerning the use of an antitoxic serum made by immunizing horses to the toxin of the typhoid bacillus indicate that it has been satisfactory from the standpoint of an immunologic experiment but so far the results do not justify the assumption that this will be a popular method of combating the disease The administration of typhoid vaccine to chronic carriers has appeared to be of little avail

Treatment of Convalescents—After the temperature of a patient has been normal for a week or ten days he is allowed to be propped up in bed and after three or four more days he is allowed to be out of bed then as his strength returns he begins very slowly with a moderate amount of exercise The diet is gradually increased during convalescence until after the first ten days it has reached its normal level Strict attention should be given to the discovery of possible carriers The treatment of carriers presents

convulsions (in children), cough pneumonia, splenomegaly, or muscle weakness may appear The course is brief usually two to five days and the mortality very low Generally there is leukopenia and cultures from the stool occasionally from the urine and rarely from the blood may be positive for *S suipestifer* Specific agglutinins appear during convalescence

Sporadic cases usually begin with an acute onset of high fever occasionally preceded by a chill In a few cases the onset is more gradual In about two thirds of these cases the bacteremia is uncomplicated by the development of focal lesions and the course

the organisms have been isolated from the sputum or from the lung at autopsy

Bone and particularly joint lesions occur in about 20 per cent of cases according to Harvey The lesion is usually a pyarthrosis with organisms present in the greenish fluid which accumulates in the joint space and with involvement of the adjacent bone Any joint may be involved and the lesions frequently occur after the acute systemic infection has subsided

Purulent meningitis particularly in children bacterial endocarditis superimposed on damaged valves pyelonephritis and abscesses in various parts of the body have

Fig 21 —Clinical course of *S suipestifer* infection in a twenty-one-year-old primiparous woman who had had a spontaneous delivery during the disease and who developed both pneumonia and arthritis of the sacroiliac joint The baby appeared ill for the first week but recovered *S suipestifer* was isolated from its stools on the twentieth day of life

is that of a typhoid like febrile disease with leukopenia and fever lasting one to three weeks Tachycardia is much more common than bradycardia and although cough coryza headache delirium stupor vomiting constipation and diarrhea all may occur as in typhoid fever they are much less frequent symptoms Intestinal hemorrhages and perforation have not been described

Focal complications are more frequently observed than in typhoid and paratyphoid fever Pulmonary lesions particularly bronchopneumonia have been noted in about one third of the cases Lobar pneumonia pleural effusion empyema and pericardial effusion have been observed In some cases

all been described as complications of *S suipestifer* infection

The characteristic laboratory findings are a mild anemia which progresses during the disease and leukopenia which may be followed by the development of a leukocytosis when focal complications appear Bacteremia occurs in a very high percentage of cases and persists throughout most of the febrile course The agglutination reaction becomes positive to a high titer in most cases Positive urine cultures are frequently obtained but positive stool cultures are rare

Diagnosis —The diagnosis of *suipestifer* infection is usually easy if the disease is kept in mind and blood cultures are taken

typhoid fever Quite a number of authors consider the frequency of respiratory complications as evidence of infection with the *Salmonella* organism

Diagnosis—Practically all authorities are of the opinion that paratyphoid fever cannot be differentiated clinically from typhoid without laboratory aid At present, agglutination tests and recovery of the organism from the blood stream are the methods of greatest importance for recognition of the disease

Prognosis—Prognosis is influenced by the same considerations pointed out in typhoid fever However the mortality rate is lower than that of typhoid fever

Treatment—Treatment does not differ in any way from that previously outlined for typhoid

SALMONELLA SUIPESTIFER INFECTION

Definition—*Salmonella suipestifer* infection is an acute illness due to organisms of the hog cholera bacillus group It may occur in epidemics as a gastro enteritis or sporadically as a form of paratyphoid fever which is characterized by a tendency to affect children or debilitated individuals by the absence of intestinal lesions and by the frequency with which bacteremia pulmonary lesions and joint involvement occur

History—Although *Salmonella suipestifer* (hog cholera bacillus) was first isolated in 1885 by Salmon and Smith from swine it was not until 1902 that infection in man was described when Longcope reported two cases of fever due to a paracolon bacillus later identified by TenBroeck as a member of the hog cholera group With the interest in enteric disease occasioned by the World War these organisms were identified as the causative agents of paratyphoid occurring in Mesopotamia among troops who had been vaccinated with TAB vaccine In recent years an increasing number of gastro-intestinal outbreaks and sporadic cases have been reported from various parts of the world

Etiology—*Bacteriology*—There are three members of the Paratyphoid C group which have been isolated from cases of this type. These are indistinguishable from *S schottmulleri* (Paratyphoid B bacillus) by the ordinary fermentation tests, but can be distinguished by their action on special sugars and by their serologic reactions in properly prepared antisera

The three species are

S hirschfeldii (Paratyphoid C bacillus Eastern type of *S suipestifer*) ferments arabinose and trehalose antigenic formula VI VII c 1 4 5

S cholerae suis (hog cholera bacillus American type of *S suipestifer*) does not ferment arabinose and trehalose does not produce H_2S antigenic formula VI VII c 1 3 4 5

S cholerae suis var kunzendorf (European type of *S suipestifer*) does not ferment arabinose and trehalose produces H_2S antigenic formula VI, VII— 1 3 4 5

Epidemiology—The source of *suipestifer* infection in man is usually hard to identify Certain epidemic outbreaks have been traced to infected meat shellfish, ice cream and other foods prepared under poor sanitary conditions and in some cases obviously contaminated with hog wastes However although the two varieties of *S cholerae suis* are natural pathogens of swine it has not been possible to trace most human infections to contact with these animals

Incidence—Susceptibility to *suipestifer* infection seems to be universal in man but the infectiousness is less marked than with the Paratyphoid A and B bacilli Thus although cases have been reported at all ages in all races the majority have occurred in children or else in adults debilitated by other diseases surgical operations or malnutrition

Morbid Anatomy—There are no specific pathologic lesions in *suipestifer* infection The findings are characteristic of any generalized infection—namely acute splenic tumor focal necrosis of the liver cloudy swelling of the kidneys and widespread petechial hemorrhages The absence of intestinal lesions has been conspicuous

Symptoms—Epidemics of food poisoning due to *S suipestifer* occur among groups who have ingested heavily contaminated food After an incubation period of six to forty eight hours there is an abrupt onset of fever headache abdominal pains nausea vomiting and diarrhea In a few cases chills

often arises as a complication of diarrheal disease when the enteric organisms seem to gain more ready access to the lymphatics and blood stream and is frequently seen in elderly patients with constipation Trauma to the urinary passages as from an inlying catheter stasis in the bladder or obstruction to the ureters predispose to infection Thus pyelonephritis in childhood is often the result of congenital anomalies of the urinary tract, in later life prostatic hypertrophy in men and pregnancy or pelvic disease in women may obstruct the flow of urine Infection may be of the ascending type when there is obstruction to the bladder outflow but usually it reaches the kidney directly by lymphatics from the colon or by the blood stream It is probable that benign bacilluria occurs frequently and causes trouble only when the added factor of obstruction leads to stasis Urinary tract infections may be caused by any of the coliform bacilli in pure or mixed culture but the majority are due to *B coli* often in combination with the *Enterococcus* (*Strep faecalis*)

Although transient bacteremia with these organisms is not uncommon during the acute phase of pyelonephritis generalized infection and persistent bacteremia are rare except in infants and debilitated elderly patients

Morbid Anatomy—Acute infection with these organisms produces purulent inflammation In cases of bacteremia in infants there is a tendency to localization in the kidneys meninges lungs and serous cavities In surgical infections pus produced by the colon group has a greenish color and characteristic fecal odor The presence of *B pyocyaneus* imparts a bluish tint to pus

Contrary to earlier opinion the lesion in pyelitis has been found to involve the renal parenchyma as well as the pelvis and ureters and so the term pyelonephritis has come into common use for this condition In the acute phase the kidneys are swollen and the capsule strips with ease revealing small yellowish raised areas on a reddish surface On section there are yellowish streaks through the cortex dilatation and redness of the pelvis and ureters Histologically acute inflammation of the mucosa of pelvis and ureters is observed with leukocytes in the collecting tubules and minute abscesses or collections of inflammatory cells in the interstitial tissue In diabetic patients with pyelonephritis gangrenous changes involving the pelvis and papillae have been described In chronic cases the kidneys become contracted as a result of scarring and secondary proliferative lesions of the blood vessels are found

Pathologic Physiology and Chemistry—All the gram negative enteric bacilli possess potent endotoxins Consequently invasion of the blood stream by these organisms is associated with the same symptoms as those which follow the intravenous injection of typhoid vaccine chills fever headache and nausea Since *Proteus* produces large amounts of ammonia from urea urinary infections due to this organism are characterized by an extremely alkaline urine and a high incidence of calculi containing calcium phosphate calcium carbonate, or magnesium ammonium phosphate

The importance of infections of the kidney lies in their tendency to become chronic and thus to produce slow and progressive renal damage In some cases severe arterial hypertension develops perhaps because the proliferative arterial lesions in the involved area produce ischemia in uninvolved portions of the kidney as suggested by Weiss and Parker

Symptoms—The symptoms of colon bacillus infection are of two types local and constitutional The *local symptoms* are determined by the particular organ infected—gallbladder bile ducts appendix urinary bladder kidney—more than by the organism concerned and detailed descriptions of these conditions will be found in appropriate sections of this book The *constitutional symptoms* are most marked in cases of peritonitis suppurative pylephlebitis cholangitis or acute pyelonephritis In these patients severe shaking chills followed by episodes of high fever malaise and nausea are the rule Where there are purulent foci leukocytosis with a predominance of polymorphonuclear cells is marked and anemia develops rapidly

The incidence of urinary tract infection is considerably higher in women than men and diabetics are particularly subject to the disease In men some obvious mechanical

in obscure cases It should be suspected whenever a typhoid like illness occurs in which pneumonia pleural effusion, or joint lesions are observed It may occur even though the patient has been vaccinated with standard typhoid paratyphoid vaccine Diagnosis is usually made by the finding of a positive blood culture or the demonstration of the development of specific agglutinins during the course of the disease

Prognosis —Prognosis depends mainly upon the condition of the patient In 1400 epidemic cases the mortality has been reported as about 0 4 per cent In sporadic cases, the fatality rate is low in children and the disease mild whereas in infants and adults over 30 the death rate is high In the presence of pneumonia the mortality among reported cases has been about 40 per cent while cases with meningitis or bacterial endocarditis have been almost uniformly fatal

Treatment —No specific treatment of this infection is known at present A three day trial of therapy with large doses of 6 to 9 Gm (grains 90 to 135) daily of sulfathiazole or sulfadiazine is justified but these drugs have not proved efficacious in most cases of typhoid and paratyphoid fever General supportive measures and surgical treatment of any purulent foci which may serve to disseminate the infection are all that can be recommended

Prophylaxis —Since paratyphoid C infections occur in individuals vaccinated with standard typhoid paratyphoid vaccine, the inclusion of *S suipestifer* in such vaccines seems indicated This is particularly important in military medicine for troops are apt to be heavily exposed to enteric infections and to be debilitated by fatigue exposure disease and wounds That protective vaccination is effective was apparently demonstrated by Hirschfeld in the last war

INFECTIONS WITH THE COLON GROUP OF ORGANISMS

Definition —The various forms of infection caused by the gram negative aerobic bacilli normally present in the intestinal tract may be considered together under this heading

Bacteriology —The colon bacilli include a number of organisms which can be isolated from normal stools The chief members of this group which are distinguished from the enteric pathogens by their ability to ferment lactose are *Aerobacter aerogenes* (*B lactis aerogenes*) *Escherichia coli* (*B coli*) and the *Paracolon bacilli* In addition two other gram negative bacilli, *Proteus* and *Pseudomonas aeruginosa* (*B pyocyaneus*) are found in feces and are apt to produce similar types of infection

Etiology —Since organisms of the colon group are normal inhabitants of the intestines it is only under special conditions that they gain access to the body cavities or tissue spaces where they may initiate infection

In the abdominal cavity surgical infections arise either as a result of actual perforation or of damage to the tissues of the bowel wall In appendicitis cholecystitis cholangitis and diverticulitis it is probable that obstruction by calculi or fecaliths is frequently responsible for the local changes which make the tissues vulnerable to infection Puerperal infections due to colon bacilli may occur as a consequence of poor obstetrical technique or of difficult labor Open wounds may become secondarily infected with gram negative bacilli particularly *Proteus* or *Pyocyaneus*

The most common disease produced by colon bacilli is urinary tract infection It

Management of urinary tract infections should include the following

1 Study of the renal function intravenous urography and if necessary cystoscopy and retrograde pyelography to evaluate the anatomical situation

2 Relief of obstruction if possible and care of disease of the large bowel

3 Forcing of fluids to maintain a free flow of urine thus washing out pus and cellular debris, whenever this is compatible with chemotherapy

4 Adequate chemotherapy to relieve acute symptoms and cure the infection if possible

5 Careful follow up study in order to recognize and treat recurrences promptly

Chemotherapy offers several possibilities MANDELIC ACID which is effective only if the urine pH is below 5.5 is taken in doses of 3 Gm (45 grains) four times a day Ammonium mandelate is usually used since it will acidify the urine itself This drug is useful in patients who cannot tolerate the sulfonamides but may cause acidosis in patients with poor renal function or *Proteus* infections in whom the urine is apt to remain alkaline Fluids should be restricted to give a daily output of approximately 1000 cc

The SULFONAMIDES are the most effective drugs for the treatment of urinary tract infections Sulfathiazole is the drug of choice because it is effective with a high fluid intake in doses of 0.5 Gm (7½ grains) four times a day in the average adult unless the infection is very severe or caused by *Proteus Pyocyaneus* or *Streptococcus faecalis* when 1 Gm (15 grains) every four hours may be necessary The dose should be scaled down proportionately in a patient with diminished renal function Enough sodium bicarbonate to render the urine slightly alkaline will not inhibit the drug and frequently will relieve dysuria and frequency It is important to emphasize the fact that chemotherapy is relatively ineffectual without an attack on the predisposing cause Thus surgical treatment of such lesions as calculi and prostatic hypertrophy is essential and in the benign infections of older patients attention must be given to improvement of the function of the large bowel

Prophylaxis—Since the organisms of the colon group are not particularly virulent except under abnormal conditions which enable them to gain access to the tissues no specific preventive measures are necessary The prevention of serious infections of this type consists mainly in the prompt recognition and treatment of abdominal disease such as appendicitis and cholecystitis the proper handling of labor and scrupulous cleanliness in the handling of open wounds Above all it is important to consider infections of the urinary tract as potentially serious since they are prone to recur and to produce renal damage and even severe hypertension in some cases

BACILLARY DYSENTERY

Definition—Bacillary dysentery is an infectious disease caused by *Bacillus dysenteriae* It is characterized pathologically by inflammation of the colon clinically by abdominal pain and tenesmus and the frequent passage of stools containing mucus pus and blood

History—Hippocrates applied the name diarrhea to the frequent passage of liquid stools and dysentery to the passage of bloody stools Galen and other ancients gave the term its present connotation by making it include tenesmus and the passage of stools containing mucus The disease can be traced in various historic epidemics especially in wars

difficulty such as neurologic bladder, prostatic hypertrophy, urethral stricture or calculus can usually be found to account for the infection

Acute pyelonephritis may be preceded by a prodromal period of several days when malaise, slight fever, dysuria, urgency and frequency are the only symptoms, or it may begin abruptly Renal infection is usually ushered in with a shaking chill followed by fever which may reach 105° F or more in severe cases Headache nausea anorexia and vomiting are common symptoms Most patients complain of pain in the back or flank and burning on urination Examination usually reveals tenderness in the costovertebral angle and enlargement of the kidney Localizing signs may be lacking at first particularly in children In some cases the onset is not abrupt but insidious and the disease may remain chronic and unrecognized for years

The course of most attacks of acute pyelonephritis is benign The symptoms usually *disappear in one to two weeks but infection* is apt to persist longer Patients successfully treated with the sulfonamides should recover in a few days but must be watched for recurrence after the cessation of chemotherapy

The *laboratory findings* include polymorphonuclear leukocytosis mild secondary anemia and pyuria The urine is cloudy with small amounts of albumin and many white blood cells The bacilli can usually be seen in the sediment Casts are rarely found and red blood cells appear only in very acute *cases or in patients with calculus* or hemorrhagic cystitis The blood chemistry is not altered except in chronic cases with renal damage Culture of the urine yields an abundant growth of the infecting organism and blood culture is frequently positive in the early stage of an acute attack

Diagnosis —Colon bacillus infection may be suspected from the odor and color of the pus if any is found and from the character of the constitutional reaction but the diagnosis can only be established by bacteriologic *methods* Blood culture should be performed in cases with high fever and a fresh specimen of urine examined and cultured in all cases of suspected urinary tract infection In women, the urine must be obtained by catheter in order to be certain that extraneous organisms are excluded

Acute pyelonephritis does not often present a problem in diagnosis but occasionally tenderness over the ureters may suggest appendicitis or pelvic inflammation Severe cases with chills fever, leukocytosis pain in the side and consequent limitation of motion of the diaphragm may be confused with pneumonia A few patients may have high fever, little local *pain or tenderness relative* bradycardia, and only slight leukocytosis giving a picture difficult to distinguish from typhoid fever a disease in which pyuria is often observed

Prognosis —In severe infections due to the colon group prognosis depends on several factors First pure colon bacillus infections have a better prognosis than mixed infections particularly in the abdomen where the presence of pyogenic cocci and anaerobic bacilli adds greatly to the severity of the disease Second the age and condition *of the* patient make *a tremendous difference* infants and elderly patients do badly Third, the type of anatomic difficulty which gave rise to the infection has a marked bearing on prognosis

In the urinary tract the degree of destruction of the renal parenchyma and the possibility of remedying the obstruction to urinary flow will influence the outcome of the acute attack and the ultimate course of the disease Urinary infections in diabetic patients and infections due to *Proteus* or *Pyocyaneus* are apt to be resistant to therapy

Treatment —The treatment of these infections should be of two types—first general supportive measures and second therapy of the local infection In the case of intra abdominal infection surgical intervention is usually necessary The sulfonamides should be given parenterally or by mouth in large doses of 1 to 1 5 Gm (15 to 22 grains) every four hours after an initial dose of 4 Gm (60 grains) in severe colon bacillus infections such as cholangitis but in the face of suppuration improvement will be slow Sulfathiazole is the most potent drug against organisms of the colon group although sulfadiazine is also effective and is better tolerated by many patients

Symptoms —Dysentery has been symptomatically classified into the following groups by Manson Bahr (1) mild (2) acute (3) fulminating (4) relapsing and (5) chronic The fulminating group may be divided into two subgroups—the choleraic and the gangrenous The symptoms of dysentery vary considerably with the severity of the disease

Mild dysentery may be merely a diarrhea although the stools usually contain mucus

The severity of *acute dysentery* varies greatly The *incubation period* is from twelve hours to seven days The *onset* is sudden with griping pain in the abdomen followed shortly by diarrhea The symptoms increase in severity and frequency and mucus appears early in the stools Within twenty four or forty-eight hours the patient passes typical dysenteric stools consisting of mucus pus and blood from five to ten times a day or much more frequently There is straining or tenesmus on account of the severe rectal irritation The temperature rises to 38° C or over There may be headache vomiting and signs of toxemia malaise or drowsiness The abdomen is tender over the colon The onset may simulate acute appendicitis operation has been performed as a result of this mistake in diagnosis

In addition to enteric symptoms a considerable proportion of cases in America are reported as showing at the outset symptoms not usually associated with dysentery Meningitic pneumonic and agranulocytic forms occur These forms described by Felsen are ascribed by him to adaptations of the disease to a new environment and virgin soil They are rarely seen in countries where dysentery is common

The *stools* in bacillary dysentery are so characteristic that a diagnosis can practically always be made directly from them a matter of great importance in the early institution of treatment

The typical stool consists of mucopus which varies in color from pale pink to bright red according to the proportion of blood The microscopic picture is different from that of any other disease and is found even in the early liquid fecal stools A coverslip preparation of a tiny fragment well mixed with saline shows an abundant cellular exudate very rich in polymorphonuclear leukocytes variable quantities of red blood cells and always a certain proportion of large cells some of which are large mononuclears while others are macrophages or clasmatocytes The last are specially important because not only are they characteristic of bacillary dysentery but being very large and often containing ingested red blood cells they are frequently mistaken for dead amebae A notable characteristic of the exudate is that the pus cells are undergoing toxic necrosis the nuclei become pyknotic and finally disappear leaving the so-called "ghost cell

Sigmoidoscopy shows the mucous membrane intensely hyperemic with grayish superficial necrosis edema is very evident and there is a profuse moist mucous exudate Positive cultures are readily obtained by swab from the mucosal surface

The *blood count* may be normal or show a moderate leukocytosis rarely above 10 000 The average counts in ninety uncomplicated cases were Shiga dysentery 12 338 mannite fermenting group 10 063 (Peking Union Medical College Hospital Series) The leukocytic picture as described by Blatt and Shaw shows a wide variation counts varied from 8000 to 20 000 averaging about 13 000 Extreme toxicity is associated with leukopenia of from 2500 to 6500 There may be an almost complete disappearance of granulocytes such cases always ending fatally *Agglutinins* appear in the blood serum usually from the sixth to the tenth day and consequently serodiagnosis is of value only in the later stages of the disease

The *fulminating forms* of dysentery are marked by a very acute onset and severe toxemic symptoms The *choleraic type* with vomiting and great loss of fluid absorption of toxins and collapse may be mistaken for cholera The diagnosis is made from the passage of mucus with or without blood from which the cholera vibrio is absent The *gangrenous form* also begins suddenly with headache vomiting pyrexia and other symptoms of severe toxemia The abdominal pain and tenesmus are very great but later may disappear as the toxemia increases The stools in the last stages are free from mucus owing to complete necrosis of the mucous membrane

Mild recurrent dysentery is manifested by a recurrent diarrhea and the passage of a little mucus and blood which persists when treatment is inadequate in the first attack

Chronic Bacillary Dysentery —Dysentery lasting for over one month is considered chronic The persistence usually results from

The bacteriology of dysentery was conclusively established by Shiga (1898) Kruse (1900) and Flexner (1900) The disease which was one of the most important of the 1914–1918 War first broke out in Gallipoli in 1915 and was responsible for a high proportion of the 120 000 casualties from sickness in that area

Incidence—Bacillary dysentery occurs throughout the world and is everywhere commoner than the amebic form Although predominantly a disease of the tropics it is more prevalent in America and Europe than was formerly supposed Felsen states that the incidence in the United States in 1937 was approximately sixteen times that reported for *1933* and that as reported cases of bacillary dysentery increase the cases of unclassified diarrhea enteritis and dysentery ' rapidly decline

Etiology—The most important factors in transmission are flies crowding unsanitary disposal of feces and food contamination especially uncooked vegetables and fruit also direct contagion, *e g* in hospitals asylums homes, and other places

Bacteriology— The bacilli credited with the causation of dysentery all belong to a natural genus which presents the following characters They are short rods destitute of flagella and nonmotile, forming no spores *not liquefying gelatin negative to Gram s* stain and fermenting glucose and sometimes other sugars and alcohols without the formation of gas (Andrewes and Inman) Four groups of dysentery bacilli are generally accepted as definitely pathogenic Shiga Flexner Sonne and Schmitz

In cultures B dysenteriae Shiga and Schmitz do not ferment mannite the other groups are mannite-fermenters

B dysenteriae Flexner constitutes a group of bacilli which can be distinguished by agglutination Five races were thus distinguished by Andrewes and Inman (1919) and named V W X Y Z Since then an exhaustive study in India by J S K Boyd ha led to a modification of this *classification and to recognition of* six races of *B dysenteriae* Flexner with a group antigen and type antigens specific to each and in addition three races named *B dysenteriae* Boyd which have Flexner biochemical reactions but no group antigen Boyd s article (1940) should be referred to for details of this complex subject

Shiga (1933) recognizes (1) *B dysenteriae* (Shiga Kruse) (2) *B metadysenteriae* (including Schmitz bacillus and the Flexner group (3) *B paradysenteriae* (Sonne)

The Shiga bacillus generally causes more severe symptoms than the others though Flexner may produce very severe dysentery The Sonne bacillus has given rise to numerous epidemics of a comparatively mild dysentery or in some cases to symptoms similar to those of *Salmonella* 'food poisoning' Shiga bacillus produces a neurotropic exotoxin as well as an enterotropic endotoxin the other groups only an endotoxin

Morbid Anatomy—The toxin of *B dysenteriae* causes acute inflammation of the whole length of the colon and the termination of the ileum, leading to coagulation necrosis of the mucosa and ulceration In chronic dysentery the distal part of the colon is affected more often and more severely than the proximal The earliest lesions are in the lymphoid follicles of the colon (Manson Bahr) which before long stand out like distinct grains of sand on a red background of inflamed mucosa (Felsen) Coagulation necrosis of the mucous layer supervenes Microscopically this is seen as a thick necrotic layer densely packed with polymorphonuclear leukocytes at the base of which are remnants of Lieberkühn s follicles The submucosa is edematous and the capillaries in it may contain macrophage cells Separation of the necrotic membrane leaves ulcers with irregular margins or in severe cases extensive raw surfaces Necrosis as a rule is superficial to the muscularis mucosae but it may go deeper in places and exceptionally may perforate the serosa

Chronic dysentery causes numerous ulcers in a thickened fibrosed mucous membrane

In healing the mucous membrane regenerates from the remnants of Lieberkuhn s *follicles but when necrosis and exfoliation* have been extensive or in chronic fibrosis severe scarring and narrowing of the lumen may ensue Mucous glands may be nipped off in scar tissue and form cysts

Bacillus dysenteriae rarely invades the blood stream though *occasional cases* have been reported

The changes *in other organs* are usually slight Parenchymatous degeneration of the myocardium is sometimes found (Blatt and Shaw) The adrenals may show degeneration of or hemorrhages into the medulla The brain is found to be slightly edematous and shows degenerative changes of the ganglion cells in cases affected by the dysenteric neurotoxin

isolation in treating patients are important factors in prevention In endemic regions vegetables and fruit should be sterilized

Vaccines—Vaccines made in the ordinary way may cause severe local or general reactions especially in the case of the Shiga bacillus Vaccines treated with immune sera or detoxicated by formalin have been recommended Besredka introduced the method of oral administration of killed dysentery bacilli Reports of the results obtained by various methods are conflicting Kauntze inoculated 50 000 East African porters without improving the death rate from dysentery Gautier (1024) however got apparently good results in a mixed Shiga Flexner epidemic by means of orally administered polyvalent vaccine and Iguchi and others (1032) using an oral vaccine on 130 000 school children during two successive years reduced the morbidity rate of dysentery by half

Treatment—Complete rest in bed is highly important Castor oil 15 cc (½ ounce) may be given early to evacuate indigestible bowel contents

Diet must be such as will leave a minimum of residue in the bowel In the early acute stage fluid intake should be as large as possible and may be given as saline or clear soup to replace loss of salt Nourishment is restricted to albumen water orange juice or cabbage water tea with lactose arrowroot or rice water Milk is unsuitable at this stage With improvement milk fruit juices and smooth cereals can be added and still later further additions should gradually be made of eggs crackers and butter custards milk puddings toast fish chicken and mashed potatoes Return to normal diet should always be gradual and full diet should not be allowed till healing is complete this is shown by complete disappearance of mucus from the feces and of leukocytes from the microscopic specimen

A breast fed infant should continue with breast feeding An artificially fed infant does well on lactic acid milk In either case milk should be stopped if the child is vomiting and normal saline given by mouth instead

Chemotherapy—The treatment of bacillary dysentery has been revolutionized by the introduction of some of the newer sulfonamide derivatives Almost uniformly favorable clinical results have followed the use of sulfaguanidine in this infection The initial dose of sulfaguanidine as recommended by Marshall is 0 1 Gm per kilogram of body weight while the maintenance dose is 0 05 Gm per kilogram of body weight every four hours until the stools are reduced to less than five in twenty four hours With the great majority of cases 5 to 6 days of treatment is sufficient Sulfaguanidine appears to be effective against all the various strains of dysentery bacilli Its most striking effect however, is against the Flexner and Shiga strains

The only objections to sulfaguanidine are that it is absorbed into the bloodstream to such an extent that it gives rise to frequent and sometimes severe reactions It is also ineffective in the presence of ulcerating lesions of the bowel

More recently succinylsulfathiazole has been introduced because of its minimal absorption from the intestinal tract When administered to patients the drug produces a profound change in the physical characteristics and the bacterial flora of the feces The stools become small in bulk semifluid and relatively odorless and the number of colon bacilli is markedly reduced Succinylsulfathiazole is only slightly absorbed from the intestinal tract producing blood levels of 0 6 to 1 0 mg per 100 cc

Smythe and his co workers found that succinylsulfathiazole was just as effective as sulfaguanidine without its potential toxic effects and therefore believe succinylsulfathiazole to be the drug of choice in the treatment of bacillary dysentery The dosage recommended is 0.25 Gm per kilogram of body weight initially followed by 0 04 Gm per kilogram of body weight every four hours for at least six consecutive days On this program 85 per cent of the patients treated were quickly cured Smythe stresses the importance of repeated stool cultures for at least three weeks after drug treatment has been discontinued From the evidence so far available it would appear that succinylsulfathiazole is just as effective as sulfaguanidine and probably less toxic If further investigation bears out preliminary observations it may prove to be the drug of choice

inadequate treatment in the acute stage or too early return to a normal diet and activity The patient constantly passes loose stools containing small amounts of mucus The condition may last for years and end in death from exhaustion or may slowly disappear Sigmoidoscopy shows the mucosa diffusely red and granular Generally there are numerous shallow ulcers Small ulcers on top of swollen papules are sometimes seen The bowel wall is thickened Sessile papillomata and polypi are occasionally found Cultures of dysentery bacilli have been obtained by the writer from swabs made directly from the ulcers in a large proportion of such cases

Bacillary Dysentery in Infants—It was first demonstrated by Duval and Basset that the bloody diarrhea of infants was due to *B dysenteriae* and this observation has been amply confirmed by Flexner and Holt and subsequently by many others The disease occurs in breast fed as well as in other infants (26 out of 237 cases in Holt s series), may be mild or severe and causes constitutional symptoms which are not always proportional to the degree of local inflammation as judged by the discharges According to Davison persistent passage of bloody stools or of stools containing much pus is practically always evidence of dysentery infection which can be demonstrated by culture or serum agglutination

Toxemia and dehydration are more severe in children than in adults The onset may be marked by vomiting or convulsions and the patient is drowsy apathetic and difficult to feed the temperature may be high and loss of weight rapid Death usually occurs in the acute stages but may result from marasmus after dysentery has disappeared

Complications—*Arthritis* mono or poly articular occurs usually in Shiga infections after the acute stage is past Other complications are bronchopneumonia in children toxic myocarditis, neuritis conjunctivitis and iridocyclitis Sequelae are anemia or edema due to malnutrition and stenosis of the colon

Diagnosis—Diagnosis of bacillary dysentery can be made from the cellular exudate seen through the microscope This should be confirmed by culture

The diseases from which bacillary dysentery has to be differentiated are amebic dysentery, balantidial dysentery schistosomiasis, malarial 'dysentery, cholera intussusception, mucous colitis ulcerative colitis tuberculous ulceration of the colon, and carcinoma Of these amebic dysentery is the commonest cause of error, but it can be distinguished by examination of the stools In a typical case of amebic dysentery the stool is liquid and reddish brown, containing shreds of mucus Under the microscope it shows comparatively few leukocytes with a preponderance of mononuclears over polymorphonuclears The leukocytes do not show signs of toxic necrosis and autolysis but are eroded from their periphery by proteolytic digestion, the nucleus disappearing last Charcot Leyden crystals are often present. Finally the diagnosis is made by finding motile *Entamoeba histolytica* containing red blood cells The commonest error is to mistake macrophages in a bacillary stool for dead amebae, and a motile *E coli* or other nonpathogenic ameba may also lead one astray *E histolytica* may be found in a bacillary exudate in a mixed infection The cellular exudate in bacillary dysentery being much more profuse than in amebic it dominates the picture

The onset may closely simulate acute appendicitis Features pointing to a diagnosis of dysentery are shift of pain and tenderness with change in the position of the body and a low leukocyte count After twelve to twenty four hours characteristic dysentery will have set in

Serum agglutination is diagnostic in chronic Shiga infections if the titer is above 1 40 it is less reliable in Flexner cases

Prognosis—Mortality varies enormously It is much higher in children than in adults In Blatt and Shaw s series of 356 children the mortality was 17 per cent During the war it did not exceed 2 7 per cent in Macedonia Egypt and Mesopotamia among the British Forces from 1915 onward The invalidism caused by the disease is considerable Although in 50 per cent of a series of typical cases diarrhea lasted only eight days the average number of days of treatment for the 2000 cases in the British Army during 1917 and 1918 was 141

Prophylaxis—Sanitary disposal of feces fly prevention food protection and strict

may be applied directly to the ulcers by means of a cotton swab

The diet in chronic cases must be bland but nourishing and when a long continued diet is prescribed it must contain sufficient protein and the essential vitamins

Autogenous vaccines are sometimes effective in chronic cases The initial dose of Flexner vaccine may be 10 000 000 bacilli subsequent doses every four to seven days may be increased up to 100 000 000 Shiga vaccine must be given cautiously commencing with not more than 5 000 000 and increasing to a maximum of 15 000 000

Surgical intervention is necessary if ulceration of the colon is present higher up than can be reached by the antiseptic solution or in the very severe cases where complete rest of the colon is indicated The first can be inferred when the patient can retain only small quantities of the solution and when cultures taken on swabs from the sigmoid continue to yield dysentery bacilli even when the visible length of bowel is improving For this condition appendicostomy is the operation of choice the upper end of the colon can thus be reached with Dakin s solution If the aim is to set the bowel completely at rest cecostomy or ileostomy may be performed The latter is most effective in that while all fecal matter is diverted from the diseased bowel the patient can be given an abundant nourishing diet and the colon irrigated with Dakin s solution through the lower ileostomy opening When the dysentery is cured continuity of the bowel can be restored by operation

Treatment of Carriers —Kirby and Rantz have shown that carriers of dysentery bacilli can be treated successfully with succinyl sulfathiazole Dysentery bacilli disappeared from the stools of five carriers during succinylsulfathiazole administration and remained absent for periods of thirty to sixty days

ASIATIC CHOLERA

(*Cholera Indica*)

Definition —Cholera is an acute specific infection involving primarily the ileum It is characterized by profuse effortless diarrhea vomiting collapse muscular cramps and suppression of urine

History —The disease has existed in India from time immemorial Invasion of other countries however did not occur until modern times the first widespread epidemic in the Orient occurring in 1817 With the increase in travel and with little knowledge of epidemiology great pandemics arose in which cholera traveled to Europe by either of two main paths (1) overland to Russia by the caravan routes or (2) by water along the trade routes of Arabia and Egypt From Europe the disease has invaded North America, and has several times appeared on the eastern seaboard and along the Mississippi Valley Cholera has not yet been carried from the Asiatic coast across the Pacific Ocean to our western seacoast

Etiology —During the pandemic between 1879 and 1883 Koch working in Egypt described the cholera vibrio In view of the insusceptibility of lower animals to cholera he was unable to apply his postulates for

Sodium sulfate in saturated solution (30 per cent) should be given in doses of 4 to 8 cc (1 to 2 drachms) every two hours day and night when the patient is awake and continued for twenty four hours or until free watery stools are passed It can then be administered once every four hours This greatly relieves the pain and tenesmus Although some physicians are opposed to it sulfate of sodium or magnesium is almost universally used in countries where dysentery is common In children or in adults suffering from dehydration sulfates must be given cautiously together with abundant fluids both by mouth and parenteral injection Normal saline subcutaneously, glucose 5 per cent in normal saline intravenously, and blood transfusions should be used as indicated As acute symptoms diminish it is important to prevent retention of feces by continuing salines or by colonic *lavage Progress at this stage is sometimes* delayed for no apparent reason and lavage of the colon with normal saline at a rectal temperature of 40° to 46° C is beneficial Chinioform (yatren) by the mouth or by rectal injection is also useful in delayed convalescence

In the treatment of children the great essential is to combat dehydration and acidosis Guy and Yeh stress the importance of replacing minerals and vitamins as well as fluids They give cabbage water with com*mon salt and calcium lactate* Scott in Tsinan has found that sodium sulfate gives good results in children provided abundant fluid from 1 to 2 liters of normal saline every twenty four hours is given to the child Sodium sulfate is prescribed in 25 per cent solution 5 cc of which is given from 2 to 5 times in twenty four hours It lessens tenesmus and blood in the stools

In fulminating cases it is above all necessary to forestall collapse by keeping the patient warm and by intravenous injections of normal saline—amounts up to 1000 or 2000 cc (40–60 ounces) In the choleraic type Roger's hypertonic saline (sodium chloride 8 Gm—120 grains calcium chloride 0 25 Gm—4 grains water to 568 cc—1 pint) *may be given* intravenously

Serum therapy is still a matter of experiment and discussion The general opinion is that serum is antitoxic rather than bactericidal and that it is more effective in Shiga than in Flexner injections It should be *reserved for severely toxic* cases and given early in the disease A dose of 40 to 80 cc is given intravenously once or twice daily with the usual precautions against anaphylaxis it may also be injected into the muscles In the writer s experience large doses are necessary and should be continued for some days until the stools are decidedly improved and both temperature and pulse have returned to normal

The treatment of *chronic dysentery* calls for patience and perseverance but no case need be considered hopeless The usual treatment by injection of mild or dilute antiseptics into the colon is practically useless in most cases Contrary to the general belief dysentery bacilli persist in chronic cases for years and the patient does not get well until they are eradicated Various methods *may be employed for this purpose* Silver nitrate in 1 to 5 per cent solution is advised by C F Martin and is effective, but safer more satisfactory and less expensive is Dakin's solution Commencing with 25 per cent Dakin s solution 300 to 500 cc at body temperature are injected per rectum thrice daily The concentration is increased according to the patient's tolerance up to full strength Dakin s solution It is essential that the solution reach as high in the colon as the disease process and it should there*fore be given in the knee chest* position if the patient is strong enough and in some cases a larger volume of solution is necessary If this is not successful surgical assistance is indicated, as described below Yatren is also curative and is much less trying to the patient It should be given as a combined oral and rectal treatment An efficient dose is 0 5 Gm thrice daily by mouth and 3 Gm in 200 cc of water by rectum The rectal injection preceded by a cleansing enema is best given at night and is easily retained until the following morning in most cases

Hot normal saline lavage of the colon at a temperature in the rectum of 40° to 46° C is of value in subacute and chronic cases

Progress of the case while under treatment should be observed by repeated sigmoidoscopy If the rectum alone is ulcerated 10 to 20 per cent solution of silver nitrate

with shreds of mucus and cellular débris Occasionally, though rather rarely this material is very finely divided so that it does not settle out and thus forms the characteristic rice water stool Shortly after the onset of the diarrhea persistent vomiting usually occurs The subsequent symptoms may be divided rather sharply into two groups—those of collapse and those of reaction

Symptoms of Collapse—A characteristic train of symptoms sets in which is closely associated with the loss of fluid from the tissues The skin loses its elasticity muscular cramps become severe, the eyes sunken the voice feeble the thirst intense the secretion of urine ceases and the respiration becomes rapid The pulse is rapid and weak the blood pressure falls and the heart sounds are feeble The skin and mucous membranes are blue and the temperature of the skin is subnormal The rectal temperature may be subnormal in algid patients but rises slowly as the stage of reaction approaches

The loss in the elasticity of the skin is first noticed over the extremities The skin of the hands may wrinkle spontaneously (the washerwoman s hand) or when a fold of skin over the back of the hand is lifted it does not spring back into position but sinks down very slowly by its own weight Paradoxically well marked wrinkling of the skin develops either after the rapid loss of fluid or the soaking of the hands in water Muscular cramps appear first in the extremities as the loss of fluid is felt there first of all Native patients commonly tie bamboo thongs around the fingers and toes with the idea of preventing the cramps from spreading upward As the cramps increase in severity additional thongs are bound around the knee and elbows Indeed when such patients are admitted to the hospital it is at once evident that the symptoms have been unusually severe and that the need of fluid is urgent The patient either loses his voice completely or is able to speak only in a hoarse whisper The secretion of urine diminishes rapidly and often ceases altogether on account of the great loss of fluid the blood pressure in the renal artery may sink below the point (40 mm of mercury) which is necessary for the secretion of urine The blood pressure falls so low that on incising a superficial vein such as the external saphenous, a few drops of dark thick blood exude but no free hemorrhage occurs The red cell count is increased by 1,000 000 or 2 000 000 per cubic millimeter on account of the concentration of the blood The white cell count rises to 25 000 and even to 50 000 or 60 000 per cubic millimeter The exact nature of the polymorphonuclear leukocytosis is unknown The poor circulation and the consequent poor aeration of the blood stimulate the respiratory center and the respiration becomes shallow and rapid The pulse rate increases the temperature remains low—a condition which is exactly opposite to that of typhoid fever with its high temperature and relatively slow pulse Some cases terminate fatally during the first few days or even hours of the disease

Symptoms of Reaction—Distinctly more than half of the patients ordinarily survive the period of collapse or as it is often called the *algid stage* The signs of reaction are largely the reverse of those of collapse The diarrhea subsides and constipation may develop The muscular pains cease the skin becomes warm and elastic the voice returns and the body temperature rises The cyanosis gives way to a bright color of the skin and mucous membrane The respirations become deep and nearly normal in rate The pulse instead of being feeble and rapid returns to an almost normal rate and it may become full and bounding The blood pressure may rise to 150 or 160 mm of mercury at systole

Interest at this stage centers largely on whether the secretion of urine commences In some patients the amount secreted returns more or less gradually to normal and a satisfactory convalescence ensues In a relatively small proportion the evidences of toxemia persist and the patient passes into a typhoid like condition which may prove fatal

Acidosis and Uremia —During the stage of reaction the secretion of urine is resumed in the majority of cases but the daily output is small (100 to 300 cc) the specific gravity is high and albumin and casts are abundant The total output may increase slowly or may diminish and then cease altogether Uremia not unlike that of ordinary nephritis proves fatal in about 15 per cent

determining the etiologic relationship of an organism to a given disease and some un certainty arose concerning the causative role of this vibrio in cholera Doubting the patho genicity of the cholera vibrio Pettenkofer and Emmerich in 1892 drank a small quan tity of a bouillon culture Pettenkofer devel oped a mild diarrhea and the vibrios were recovered *from the watery stools*, but he maintained his skepticism concerning their etiologic role Emmerich developed a severe attack of cholera which nearly cost him his life Aside from this experiment there have been several accidental infections with the cholera vibrio The presence of virulent strains of *Vibrio cholerae* in the intestinal tract, however, does not always lead to the development of symptoms

Bacteriology—*Vibrio cholerae* grows readily on simple media, particularly if the reaction is neutral or slightly alkaline It is easily stained and is decolorized by Gram's method The organism is readily killed by heat drying, and disinfectants In freshly *isolated cultures the vibrios are extraordi* narily motile

The cholera vibrio is imitated precisely in its morphology *staining and cultural char* acteristics by vibrios which are found in the intestinal tract of man and also as free living *forms in nature At the height of an epid* emic the characteristics of the 'true chol era vibrio are well marked and it can be distinguished from other vibrios by the utili zation of Pfeiffer s phenomenon or by agglu tination tests with a specific serum prepared from a known strain of cholera Nonagglu tinable vibrios predominate during the inter epidemic periods and they are also found in the early and late stages of an active out break of cholera their relationship to the agglutinable strains is still unsettled The injection of moderate amounts of a cholera culture into the tissues of experimental ani mals such as guinea pigs or monkeys pro duces death in a few days but does not produce the clinical syndrome of cholera the ingestion of cultures by lower animals produces no effect except under highly arti ficial conditions

Epidemiology—For its propagation in nature *Vibrio cholerae* as far as we know depends entirely upon man The organism soon dies out in nature in competition with free living forms and is not har bored by any of the lower animals At the beginning of an outbreak, both the symp toms of the patient and the accompanying vibrios are often atypical, as the epidemic progresses, characteristic symptoms develop and the vibrios agglutinate typically The interepidemic periods are probably bridged over in part by human carriers but the pro portion of carriers after an epidemic is not large and the carrier stage is of relatively short duration This explanation of the in terepidemic periods is not especially satis factory and it is evident that the nonagglu tinable strains of vibrios must be given serious consideration

Seasonal Variation—A warm and moist climate favors the spread of cholera

Morbid Anatomy—An early and extreme grade of *rigor mortis* occurs in cholera A dusky cyanotic color of the skin, the finger nails, and the mucous membrane is notice able On incising the abdominal wall one is struck by the dryness and deep color of the tissues Instead of a little free *fluid in the* peritoneal cavity and the other serous sacs only a sticky residue remains The urinary *bladder is empty The ileum* particularly the lower portion may be reddened As a rule the ileum contains an abundant amount *of rice water material* though its contents may vary from a little bile stained mucus to dark purple blood tinged fluid The lymphatic tissue is prominent Histologi cally there is a subepithelial edema of the small intestine *Antemortem* desquamation of the epithelium is rare The renal lesions are mild in proportion to the severity of the uremic symptoms The kidneys often show parenchymatous swelling with an irregular cortex and distorted striations The wet brain of uremia is sometimes encountered Invasion of the gallbladder is common in fection taking place by direct *extension* from the duodenum

Symptoms—The *incubation period* is *short* but *variable ranging from* a few hours to five or six days

Onset—The disease may be ushered in with a preliminary warning which consists of one or two days of diarrhea or the onset be sudden with violent purging As the fecal matter is quickly cleared from the bowel the stools consist of almost clear water

ries distinctly not only in different epidemics but during the course of a given epidemic, being greatest as the outbreak reaches its peak Under ordinary conditions with patients coming under treatment rather late in the stage of collapse a mortality of 50 per cent may be expected but in exceptionally severe circumstances the death rate may be even higher Of this number about 30 to 35 per cent die in the stage of collapse and it may be expected that 15 per cent will die of uremia unless alkalis are used intensively Under more favorable circumstances when the patients report early for treatment the mortality may be restricted to 20 or 25 per cent

Prophylaxis —Cholera is spread in much the same general manner as typhoid fever The vibrios leave the body by way of the feces and the vomitus Epidemics and pandemics of cholera have arisen with a severity unknown in typhoid fever and at times these outbreaks have spread with terrifying rapidity However the disease cannot travel any faster than man travels and an outbreak is usually amenable to preventive measures

Control of an epidemic of cholera can be brought about by (1) protection of the supplies of food and water from contamination (2) destruction of the excreta of patients (3) prophylactic inoculation for reducing the susceptibility of the population The individual can protect himself with comparative ease in times of an epidemic The recommendation to use only *hot food* and *drink* is particularly good The vibrios are easily killed by heat but food and water though properly heated may after cooling become seriously contaminated in a very few hours. In several tropical communities the public has been instructed thoroughly in preventive measures and the educated adult who contracts cholera frequently receives little sympathy from the community in general

For *specific protection* against cholera suspensions of vibrios killed by heat may be injected subcutaneously without any more inconvenience to the individual than if sterile saline had been used It is probable that a moderate degree of protection exists for a few months after inoculation This in itself would be of great assistance in controlling an epidemic The vibrios are limited almost entirely to the intestine and the theoretical basis for vaccination is less evident than in typhoid fever

Attempts have been made to protect communities by treating the water of village wells and cisterns with vibriophage

Treatment —There are three objects to be accomplished in treatment namely, (1) the relief of toxemia (2) the restoration of fluid (3) the prevention of acidosis and uremia

Many *specific antitoxic sera* have been prepared for cholera but they have not proved of value Until the nature of the toxemia is understood it will be difficult to provide specific treatment Attempts have been made to utilize vibriophages for specific therapy and the idea has been advanced that only those patients recover who receive phage or who develop their own phage This view has not yet been established

The *restoration of fluid* is undertaken by intravenous injection of salt solution Usually 2 liters of saline are given in the course of fifteen or twenty minutes The immediate effect is striking the blood pressure rises the pulse and respiration become slower the skin becomes less cyanotic and resumes its elasticity the patient instead of tossing about restlessly lies quietly and comfortably in bed the voice returns The first request is usually for a glass of water This does not mean that the injection of saline has made the patient thirsty but rather that with increasing comfort he is able to make his wants known Very few of these patients however proceed to an uninterrupted recovery On the contrary the profuse diarrhea continues and unless the supply of fluid is maintained the symptoms of collapse return often with increasing severity An average patient requires the intravenous injection of 2 liters of fluid every six or eight hours for one or two days Some patients apparently moribund may require injections of this amount of fluid every two or three hours for a day or more One of the gratifying features of treatment is that apparently hopeless patients may unexpectedly react and make an uninterrupted recovery On one occasion a patient who was semicomatose on admission received 28 liters in the first twenty four hours he then reacted satisfactorily and

of all patients who contract cholera It was first shown in Asiatic cholera that uremia is closely associated with acidosis The carbon dioxide content of the blood diminishes markedly and the tolerance to sodium bi carbonate is greatly increased In the midst of an epidemic the clinical course of cholera is fairly uniform The severity of the disease and the mortality rise to a peak during an epidemic and then decline As already noted a small percentage of individuals though in fected with virulent vibrios, develop no symptoms Occasionally a prodromal diar rhea develops without consequent severe symptoms Rarely the disease proves fatal without diarrhea In this condition known as *cholera sicca* the bowel at autopsy is fre quently filled with rice water material In young children the symptoms are less se vere and the mortality is lower than in adults A slight but definite meningismus is of frequent occurrence though the meninges remain free from any infection

Cause of Symptoms —There is no evi dence that cholera vibrios produce a potent soluble toxin *in vitro* and the assumption of an endotoxin acting *in vivo* rests on hypo thetical grounds However cholera vibrios multiply high up in the ileum where ordi nary bacteria do not colonize and there is experimental evidence of the formation of toxic proteoses in the algid stage of cholera It has been suggested that desiccation may account for all of the symptoms including the signs of toxemia In this connection it is interesting to note that travelers lost in the desert may develop symptoms suggestive of the collapse of cholera Under these circum stances the restoration of fluid usually pro duces prompt and permanent relief in con trast to the temporary benefit observed in cholera The extremely rapid loss of water and salts from the tissues presents an oc casion for the study of the effects of dehy dration and of salt imbalance that is quite unequalled by clinical opportunities avail able in other infections

Complications and Sequelae —Asiatic cholera does not produce destructive lesions and ordinarily leaves no serious aftereffects although in American and European pa tients the return to full health and vigor may be protracted over several weeks or months Just as in acute nephritis from other causes the renal lesions do not become chronic, indeed, normal renal function is often restored quickly Cholera usually causes abortion, the muscular cramps which appear first in the extremities develop also in the uterine musculature The intestinal lesions heal readily and no after period of diarrhea or constipation is to be anticipated In the great majority of cases the vibrios disappear promptly from the stools A small but important number of patients remain carriers for weeks and even months but not for years

Diagnosis —During an epidemic any pa tient who suddenly develops coma or col lapse should be sent to the cholera hospital for observation Acute diarrhea following poisoning by alcohol, or mushrooms or accompanying food poisoning so called requires differentiation In these conditions vomiting usually precedes the diarrhea whereas the reverse is true in cholera An accurate diagnosis can be made only by bacteriologic methods Since agglutinins ap pear in the blood rather late in the disease reliance is placed on the isolation of cholera vibrios from the stools and their identifica tion by agglutination with a specific serum The vibrios occur in such great numbers in the stools and grow so rapidly that routine diagnoses are easily obtained in twenty four hours The usual method for the examina tion of stools consists in the inoculation of peptone water with a little rice water ma terial The vibrios if present grow abund antly near the surface of the liquid After eight hours it is sometimes possible to make an agglutination test directly on this fluid culture though it may be necessary to sub inoculate this enriched material on an agar plate and examine individual colonies

For the examination of carriers a selective medium is very helpful The standard me dium for this purpose is a very strongly alkaline blood agar (Dieudonné s) This allows free growth of various vibrios and of some of the streptococci but restrains ef fectively the great mass of fecal bacteria In the examination of carriers it is impor tant not to use purgatives for after taking magnesium sulfate carriers have been known to develop a typical fatal attack of cholera

Prognosis —The mortality in cholera va

plague appears to be confined to regions where the climate is temperate by virtue of latitude or elevation A relationship between plague in man and plague in wild rodents was first demonstrated by officers of the United States Public Health Service near San Francisco California in 1908 It has been assumed but not proved that the infection of the wild rodents in California was a sequel to the introduction of plague into San Francisco from the Orient in 1900

Subsequently, the existence of sylvatic plague has been demonstrated in many counties of California and in parts of twelve of our Pacific and Mountain States (Meyer 1942) Important recent information on sylvatic plague in the United States has been published by the United States Public Health Service and by Meyer Sylvatic plague is chiefly of importance as a source of infection for house rats which may then initiate outbreaks of the disease in man It is probable that sylvatic plague is spreading in the United States and that its true extent in this country and elsewhere is still unknown Only 40 human cases of plague in the United States had been attributed directly to infection from sylvatic sources up to 1938 (Eskey 1938)

Etiology and Epidemiology —Infected rodents through the agency of their ectoparasites constitute the reservoirs from which bubonic plague spreads to man and occasionally to other animals either wild or domestic Epidemics of plague in man are *generally preceded by epizootics* in house rats or mice but outbreaks of human plague in South Africa in Argentina in Russia and in China have been attributed directly to sylvatic sources Wild rodents of various genera including ground squirrels marmots gerbilles and cuis (related to the guinea pig) are subject to plague Plague travels in infected rats which frequently accompany shipments of grain by land or water

The distribution and seasonal prevalence of plague are determined largely by local and seasonal prevalence of the chief vector *Xenopsylla cheopis* the rat flea Various other kinds of fleas which attack rodents are capable of transferring plague to man and other biting insects are suspected of transmitting it occasionally That plague can be transmitted to man by *Pulex irritans* is considered probable by some authorities and doubted by others The Plague Commission of the Government of India in 1908 reached the conclusion that ingested food plays no part in the spread of the plague in nature, either from rat to rat or from rat to man Furthermore the experiments of this Commission seemed to prove that neither direct contact with cases of bubonic plague nor with fomites contaminated with the excreta of such cases was dangerous

A varying but usually small proportion of cases of primary pneumonic plague occurs along with epidemics of bubonic plague Probably these cases originate from bubonic or septicemic cases in which pulmonary lesions have developed Primary pneumonic plague is very readily transmitted directly from man to man through the agency of droplets expelled by coughing

Control.—Since the establishment of international quarantine regulations plague has disappeared from many of the seaports in which it used to be common Epidemics of bubonic plague are controllable by quarantine isolation of cases and suspects and destruction of rats and their parasites Control of pneumonic plague presents no great difficulty except under such conditions as occurred in Manchuria during the winter of 1910–1911 (Strong *et al* 1912) At that time very cold weather overcrowding in the homes of the poor and other unsanitary conditions combined to favor the spread of this form of the disease Efforts to exterminate rats and their parasites are of short lived value unless accompanied by wholesale rat proofing of dwellings warehouses and other buildings in which rats breed Information about this from Java was published in an official report by Rosier (1937) Campaigns of destruction of wild native rodents subject to plague in California as yet afford no hope of the eradication of the sylvatic infection in the United States

Although extensively used in India for many years the Haffkine vaccine which is made from killed cultures has proved unsatisfactory as a means of limiting the spread of plague Otten (1940) and other workers have reported good results from the use of a vaccine containing attenuated living plague bacilli A single dose of this vaccine is said to produce a higher degree of immunity in

made an uninterrupted recovery The inspection of the patient, the character of the pulse, and the amount of fluid lost by the bowel serve as adequate guides for the frequency of injections Various tests have been devised for this purpose such as the determination of the specific gravity of the blood In the opinion of the writer, fluid should be supplied freely before the specific gravity of the blood is increased beyond normal limits

Acidosis and Uremia—The urine often remains sharply acid in cholera even after massive injections of sodium bicarbonate (90 Gm within twenty four hours) In a normal person 5 Gm of bicarbonate ordinarily renders the urine alkaline Investigation has demonstrated the existence of an acidosis in the sense that the fixed bases of the blood and other tissues of the body are depleted Prompt restoration of these bases leads to significant results in the treatment of patients During the stage of collapse a slightly alkaline solution (0.5 per cent sodium bicarbonate and 0.5 per cent sodium chloride) may be used intravenously As the stage of reaction sets in the quantity of bicarbonate should be increased (to 1 5 or 2 per cent) and the chloride omitted The injections of bicarbonate should be continued until the urine becomes alkaline or until it is very liberally secreted Instead of the expected mortality of 15 per cent from uremia the early and persistent use of alkalis has practically eliminated death from uremia in private practice where patients report promptly for treatment A mortality from uremia as high as 4 per cent may occur in hospital practice with its proportion of patients admitted in late stages of infection

General Measures—The patient is naturally glad to remain in bed During the algid stage hot water bottles and light blankets afford the much desired warmth The vomiting which during the first days of the disease prevents the administration of even water by mouth may be checked temporarily by small doses of *cocaine* (⅛ grain) by mouth *Digitalis* is very useful in regulating the action of the heart During the period of convalescence small amounts of liquid food are given but solids should be added

PLAGUE

Definition—Plague is an infectious disease caused by *Pasteurella pestis* the *Bacillus pestis* of Yersin It is primarily a disease of rodents and the several species of the rat which frequent human dwellings and warehouses are susceptible

Geographic Distribution—According to Wu Lien-Teh (1936), central Asia is probably the original home of plague, and the present pandemic first gained momentum on reaching Canton and Hongkong in 1894 He believes that Africa, the Philippine Islands Australia and the Americas were first invaded since that date According to his map of the distribution of plague in 1934 important active foci of bubonic plague existed in Transbaikalia (Manchukuo), in Shansi Shensi and Fukien provinces in China and in Burma, Siam, Indo-China Java India and Ceylon

Figures on the incidence of plague in 1941 and 1942 which have been published in the Reports of the United States Public Health Service are far from complete Comparatively few cases of plague were reported from China during the period Considerable numbers of cases occurred in British East Africa Morocco Madagascar the Dutch East Indies and India and there were significant numbers of cases in Brazil Argentina and Peru

The history of plague in the Americas has been presented by Moll and O Leary (1940) and they have provided detailed information about the disease in various Latin American countries (ibid 1941 and 1942)

Sylvatic plague signifies plague which is enzootic in rodents other than those of domestic habit It occurs particularly in sparsely populated regions where at intervals of years it causes explosive outbreaks among burrowing rodents Thus far sylvatic

temperature to about 120 or over, and the respiration rate to 30 or 40 per minute Co incidentally the malaise increases there may be vomiting or diarrhea and pain be comes severe at the site of the developing bubo The face is drawn and anxious The tongue is furred and sordes appear on the gums and lips The gait becomes staggering and mental dulness and physical prostration are very pronounced There may be wild or muttering delirium The temperature curve is very irregular It generally shows marked morning remissions and in cases of recovery it falls after a few days by lysis In fatal cases it may shoot up suddenly or fall critically and then shoot up again to 107° F Rapidity of the breathing is pro nounced even though the lungs may show no more than scattered moist rales Pleuritis or pneumonia may develop secondarily

Herpes does not occur The spleen is easily felt as a rule and the liver may be palpably enlarged The abdomen is tender only when the intra abdominal glands are markedly enlarged The skin is hot and dry and often shows petechiae or ecchymoses Less frequently pustules vesicles necroses or a carbuncle are seen There may be hem orrhage from any of the mucous membranes or from the kidneys

The buboes generally become manifest within twenty four hours of the onset They may subside or suppurate Rarely the infec tion is first manifested by acute inflamma tion of the throat In such cases the buboes generally develop in the neck Some cases of bubonic plague are so mild that the patient may continue to walk about for several days or even through the entire course of the illness Such cases are apt to appear at the beginning of an epidemic or when it is subsiding Very rarely bubonic inflamma tion due to the presence of *Pasteurella pestis* may persist for several months Purulent encephalitis may occur and a case of chronic relapsing latent meningeal plague has been reported

In the primary septicemic type of plague the constitutional symptoms are the same as in the bubonic type This form of the disease usually runs a rapidly fatal course without the development of buboes Plague bacilli may be so numerous in the blood as to be demonstrable in stained blood smears

The primary pneumonic type of plague is characterized by the rapid development of a lobular pneumonia which becomes con fluent and thus produces extensive pul monary consolidations The sputum is blood stained but watery whereas in other kinds of pneumonia it contains much fibrin and is in consequence viscid and sticky Primary pneumonic plague is nearly always fatal within a few days Its incubation period is from one to three days

Clinical Diagnosis —The possibility of plague should be considered in the presence of an acute and painful adenitis not clearly due to venereal infection and such suspicion should lead to adequate bacteriologic exam inations One should be alert to the pos sibility of plague in seaports or other communities where plague has occurred The widespread distribution of infected rodents in rural areas in many parts of the world should not be forgotten There have been notable examples of failure to diagnose plague through failure to suspect its presence until after an epidemic was well under way

A venereal bubo can usually be differen tiated from plague by the presence of a soft chancre on the penis or by the hardness of the glands and the absence of sensitive ness which characterizes syphilitic adenitis Lymphogranuloma inguinale is common in the tropics and not uncommon in the tem perate zone Its onset is more gradual than that of plague constitutional symptoms are comparatively slight and the bubo is seldom very painful Bacteriologic examinations are entirely negative but the Frei test is usually positive

Tularemia and streptococcus infections may closely resemble plague Skilled bacte riologic examination is required to differen tiate them Acute infectious mononucleosis differs from plague in that its onset is more gradual the constitutional symptoms milder the adenitis less pronounced more general and less painful and the blood pic ture characteristic

The acute constitutional symptoms of severe typhus fever malaria or other over whelming infection may resemble those of septicemic plague Influenza pneumonia may simulate pneumonic plague but the character of the sputum serves to differen tiate them

man than two doses of a killed vaccine The mortality of individuals who have become infected after the vaccination is believed to be lower than in the unvaccinated Although living vaccines have been in use for several years and untoward effects from them have not yet been reported some doubt as to their safety is still justifiable

No form of vaccine confers complete immunity but the mortality in those infected has been decidedly lower in the vaccinated than in the unvaccinated Because the duration of the protective effect diminishes after a few months it seems advisable to withhold vaccination until exposure is imminent

It is probable that some degree of passive immunity lasting not more than a few days is conferred by the injection of antiplague serum Recovery from plague confers a degree of immunity which protects from a second attack or causes subsequent infection to run a mild course

Individual Prophylaxis—Persons likely to be exposed during an outbreak of plague should be vaccinated promptly Because infection may occur through an abrasion or perhaps through unbroken skin persons who examine the bodies of plague suspects carcasses or diseased tissues should do so with extreme caution They should wear rubber gloves These precautions should be observed also by physicians or others whose duties bring them into contact with suppurating lesions

Inasmuch as infection by ingestion seems not to occur it may not be necessary to disinfect the urine or feces of plague cases Because primary bubonic plague is frequently associated at some stage with pulmonary lesions it would seem desirable to isolate all cases of plague infection

Primary pneumonic plague requires extreme precautions against infection Any person attending these patients should wear a thick close fitting mask and goggles and a uniform which should afterwards be removed promptly and sterilized Rubber gloves are also recommended

In regions where sylvatic plague exists the most necessary precaution is to avoid contact with sick rodents and their parasites However inapparent plague infection has been shown by the United States Public Health Service to exist in rodents so that complete safety involves avoidance of all contact with them and with their parasites

Morbid Anatomy—A small vesicle or a carbuncular lesion may develop on the skin at the point of infection but such lesions are rarely seen The lesions found at autopsy in typical cases of bubonic plague are characterized by marked congestion and hemorrhagic edema of masses of lymphatic glands and particularly of the group of glands draining the region where primary infection occurred There is also edema and extravasation of blood into the periglandular tissue Such buboes are found in about 75 per cent of cases of plague The petechial spots which commonly occur on the skin and mucous membranes are caused by injury to the endothelium of the blood vessels Hemorrhages may occur also on the meninges in the brain or in the spleen Usually the heart is dilated and shows fatty degeneration The larynx, the trachea the kidneys and other internal organs show intense congestion The spleen is considerably enlarged in most cases The tonsils are not markedly inflamed as a rule Occasionally they are the seat of the primary infection The glands of the neck then show enlargement

The inflammation in primary pneumonic plague spreads from the bronchial mucous membranes to the peribronchial tissues and thence to the alveoli where it sets up a lobular pneumonia which later becomes confluent The glands at the bifurcation of the trachea are much more inflamed than are the lymphatic glands elsewhere

Symptoms—Three clinical types of plague are commonly recognized namely the bubonic the septicemic and the primary pneumonic

The bubonic type is characterized except in mild cases by very painful inflammation and swelling of the lymphatic glands of the groin the axilla or the neck In the great majority of cases the adenitis is most manifest in the groin The incubation period of this form of plague is from two to ten days There may be prodromal symptoms consisting of malaise headache giddiness and pain in the back and limbs Usually the onset is abrupt the temperature rises within a day or two to 103° or 104° F and there are attacks of shivering rather than pronounced chills The pulse rate rises with the

History.—William Burnett in 1814 published an excellent description of the disease commonly known as "the Bilious Remittent Fever of the Mediterranean" and recorded autopsy findings He distinguished between this disease and malarial fevers by the failure of the former to respond to bark infusions Marston in 1863 used the term Maltese fever for Mediterranean remittent fever which he differentiated from typhoid

Bruce isolated a coccoid organism from the spleen in 1886 and transmitted the disease to monkeys with the culture

In 1897 Bang isolated a similar organism as the cause of contagious abortion in cattle but it was not until 1918 that Evans recognized the relation of Bang s organism *Bacillus abortus* to Bruce s *Micrococcus melitensis*

Infection in man was first observed among goat herders and persons who consumed goat s milk, then among veterinarians and finally in the general population Bevan in 1922 noted cases in Rhodesia apparently connected with contagious abortion of cattle In 1924 Keefer described the case of a young man with unexplained fever from whose blood culture brucella organisms were grown It was thought at first that the patient contracted the infection from eating cheese but it was found later that he became infected probably by handling fresh tissues from hogs

Etiology—The exciting cause is a minute nonmotile gram negative pleomorphic organism appearing sometimes as a coccus and sometimes as a small bacillus growing slowly on first isolation and requiring special medium It does not ferment sugars It is very resistant to drying The three varieties are *Brucella abortus caprinus* (goat) *Br porcinus* (hog) and *Br bovinus* (cattle) The varieties differ in resistance to bacteriostatic dyes and immunologic reactions also strains in the same variety are not immunologically identical

Pathology—The changes found in general infections without specific lesions are described The liver and spleen bear the brunt of the infection In the liver in addition to the small areas of focal necrosis and small foci of reticulocytes and lymphocytes there are areas of endo and thrombophlebitis with discrete and confluent granulomata resembling tubercles The latter are found also in the spleen with exudative and sclerotic areas Occasionally there are small ulcers in the intestinal mucosa and small focal necroses with lymphocytic infiltrations in the kidneys and the lungs

Epidemiology—The reservoir of the infection is in goats cows and hogs Man contracts the infection by drinking unpasteurized milk or handling infectious material In man the organism is given off in the urine (10 per cent of cases) and in a few cases in the feces There are human carriers in the sense that in the chronic stage the organisms have been cultured from the stool in a few instances but no case has been traced to infection by a carrier The organisms have been recovered from human milk The organism is very resistant hence it is possible to contract the infection from butter and cheese made from contaminated milk

Cases occur in all ages except during the nursing period of infancy More cases are observed in males than females Veterinarians goat herders farmers packing house employees and laboratory workers are especially liable to infection

The disease occurs at all months of the year but is more frequent in summer probably because of heavier contamination of milk at this period In 1935 there were reported 1897 cases in the United States with the highest incidence in Iowa There are undoubtedly many more cases Of the organisms isolated from blood cultures abscesses urine and stool 70 to 93 per cent were porcine and the remainder bovine except for an occasional caprine strain from imported cases The porcine strain also infects cattle and is transferred to man by cow s milk As the porcine strain is more invasive for man than the bovine the infection may be transferred by milk containing a relatively small number of organisms whereas milk heavily contaminated by the bovine strain may not transmit the infection Pasteurization kills the organism

Symptomatology—*Incubation Period*—The time between exposure to a possible source of infection and the onset of actual symptoms has been observed to be from five days to one month but is usually about two weeks

Mode of Onset—UNDULANT TYPE—Mild symptoms of general malaise muscular and cervical pain anorexia and headache with evening fever gradually increase in intensity for about ten days after the manner of typhoid fever

Course of the Disease—As the temperature reaches 104° to 105° F the symptoms are intensified The patient is irritable and restless and there is marked sweating usually in the morning He complains of extreme weakness is in low spirits and cannot

Laboratory diagnosis depends ultimately upon the isolation of *Pasteurella pestis* A provisional diagnosis can be made in bubonic plague by puncturing the gland with a large needle, abstracting gland juice or preferably a little gland tissue, and staining it on a slide with Loeffler's blue or dilute carbolfuchsin *Pasteurella pestis* is a bipolar staining, ovoid organism After the gland has become soft, the organism may not be demonstrable except by culture

In cases of septicemic plague the organism may be demonstrable in blood smears and in pneumonic plague the sputum is loaded with them in almost pure culture *Pasteurella pestis* can often be cultivated on the usual laboratory media from the blood of man in cases of the bubonic type of plague even when mild Cultures and guinea pig inoculations can be made from gland juice blood or sputum The macroscopic lesions in the guinea pig the rat, or the mouse are, usually, characteristic but cultures should also be made from the test animals because various other organisms may produce plague like lesions in animals Similar difficulties may be encountered in diagnosing plague in other rodents Plague infected rodents may even show no pathologic evidence of disease Mass inoculation of organ samples or of rodent parasites into guinea pigs, may then be required to detect the presence of *P pestis*

Prognosis *—Mortality from the bubonic* type of plague commonly varies in different epidemics from about 30 to 75 per cent Individual cases may be fulminant or mild The prognosis is better for persons recently vaccinated Septicemic plague as a rule is rapidly fatal Primary pneumonic plague is almost always fatal Cases of secondary pneumonia in plague may recover

Treatment —Antiplague serum made from horses has long been used with some success in the treatment of bubonic plague Living and highly antigenic cultures are required for the production of active antiplague sera Serum therapy has yielded good results in bubonic cases when administered within the first few days of illness With each succeeding day the chance of benefit decreases until the fourth or fifth day after which serum is useless It is useless also in primary pneumonic and septicemic cases

Doses of 30 to 40 cc administered intravenously seem to have given good results Larger doses of 100 to 250 cc have been recommended but, when given intravenously these large doses may cause serious circulatory disturbances The dose is to be repeated, when needed, after six or eight hours

Decidedly encouraging results were obtained by Norman Walker in 1937, using serum of convalescent patients The use of iodine whether by mouth or intravenously seems to be without benefit Use of the sulfonamide derivatives is in the experimental stage Wagle *et al* (1941) believe that mortality can be significantly reduced by the use of sulfapyridine or sulfathiazole

BRUCELLOSIS

(Undulant Fever Malta Fever Mediterranean Fever Goat Fever Dust Fever)

Definition —An acute and chronic disease of varied duration with protean manifestations characterized by fever weakness sweating and aches caused by general infection with a member of the abortus group *of micro organisms*

leading to unnecessary operation orchitis less commonly prostatitis and vesiculitis

Other Clinical Varieties—Brucellosis is protean in its manifestations There is great variation in the clinical picture exhibited by cases contracting the infection from apparently the same source

Brucella Infection of Short Duration—The fever may last only six days but the weakness and irritability may endure for weeks The diagnosis is made by blood culture It is probable that many of these cases escape diagnosis and are regarded as influenza

Ambulant Type—A large number of infected persons although feeling somewhat ill with slight feverishness fatigability weakness and headache continue to work The diagnosis is made later by the presence of a high agglutination reaction or positive skin reaction

Asymptomatic Type—Huddleson and Johnson found agglutination titers from 1 50 to 1 500 in the serum of twenty eight out of forty nine veterinarians examined Only three of them gave a history of past illness which resembled brucella infection In addition the serum of two students had agglutinins of 1 200 and 1 500 with no symptoms except a cold and tonsillitis in one of them

McBryde studied the serum of children in an orphanage where infected milk was used There were a certain number who had no illness but agglutinins of significant titer were found in their serum and continued to be present so long as contaminated milk was served The agglutinins disappeared when pasteurized milk was used Dooley has also studied the agglutinins in subclinical cases

Cases with Recurrent Mild Symptoms—A very mild form of the undulant type may not be recognized as brucella infection but be mistaken for psychoneurosis tuberculosis endocarditis or malaria Complications from brucella do occur in these cases and often the diagnosis is made only after an intensive study

Temperature Curve—The undulant type consists of several waves of fever similar to those of infectious mononucleosis In other cases the temperature may be sustained with occasional dips or it may simulate the curve in typhoid fever or malaria In the chronic stage the temperature may not exceed 100° F even when the blood culture is positive

Complications—Arthritis often occurs during the acute and chronic stages Baker found brucella in the joint fluid of a case of double recurring hydrarthrosis of the knees The original mild attack occurred seventeen years previously

A case of brucella spondylitis simulating Pott s disease has been reported Various long bones and in 1 instance the small bones of the wrist have been involved D T Smith reported a case of brucella meningitis with recovery Endocarditis is not infrequent and may simulate in every way subacute bacterial endocarditis Pericarditis has been reported in one of these cases and mycotic aneurysm of the basilar artery was discovered at necropsy in two cases Amoss likewise Gilbert and Coleman have isolated brucella from aspirated bile A culture from suppurative cervical lymphadenitis simulating tuberculous infection yielded brucella

Brucella has been isolated from the urine in cases with initial symptoms of cystitis and renal tuberculosis and from uterine discharges following abortion Amoss reported a case of chronic brucella peritonitis with tuberculous salpingo-oophoritis and a case in which this organism was recovered from a small cyst on an otherwise normal ovary Mastitis is not an infrequent complication Chronic subcutaneous abscesses have yielded a pure culture of brucella in several instances The organism has been isolated once from pleural fluid Uveitis as a complication has been observed frequently in epidemic areas

Diagnosis—In acute cases a tentative diagnosis is often made by the clinical signs already enumerated and is confirmed by blood culture To avoid the inhibitory effect of the patient s serum a small amount of blood is placed in a large amount of liver broth A flask and plate should be incubated also in 10 per cent CO_2 Growth may not be apparent for eight or more days Before discarding as negative the cultures should be incubated for eighteen days Intermittent bacteremia may be present even when there is very low grade fever hence repeated blood cultures may be necessary

sleep The tongue is coated but the edges and tips are clean Constipation is usually marked and there is often a slight bronchial cough The pulse rate is generally consistent with the fever but relative tachycardia or bradycardia may be present Dicrotism is rare Slight leukopenia is the rule with diminution especially in the myeloid elements and relative increase in mononuclears, some of which may be pathologic The white count in some cases may be very high with a marked increase in small lymphocytes The spleen may be slightly enlarged to percussion and in a small percentage of cases is palpable The clinical picture with leukopenia catarrhal symptoms and occasionally epistaxis or intestinal hemorrhage may at this time suggest typhoid fever but the apathy, headache red tongue and rose spots are absent Moreover, within a day or so the temperature begins gradually to decline and there is a slight clinical improvement Another feature which is useful in arriving at a tentative diagnosis of undulant fever is the sudden appearance in the majority of cases of intense sacro iliac pain or sciatic neuritis which endures for three or four days Joint pains with tenderness and swelling especially of the knee ankle hip and shoulder are often present and last for a day or so to return in the later phases of the disease

Blood cultures with special technic for *Brucella* are positive Incubation for at least ten days is necessary and frequent transfer to solid medium during this period determines the presence of organisms

Agglutinins to one or more stock strains of brucella usually appear in the patient s serum after the first week but may be absent throughout the course of the disease It is important to set up high dilutions as the proagglutinoid zone may be present in as high a dilution as 1 1200 If the titer is below 1 100 serum should be taken five to seven days later for a retest If the reaction is then present in higher dilutions the test is of significance Because of the great antigenic differences in the members of the brucella group several stock strains (at least three of each variety of *Brucella abortus*) should be used Cases have been observed in which agglutination was positive with only one of eleven antigens used in testing Agglutinins may be absent or they may disappear during the course of the disease On the other hand they may reach a dilution of 1 20,000

Subsequent Course—The fastigium is very brief The fever curve from the onset reaches a higher point each evening and the morning remission is less As the evening temperature reaches 104° to 105° F it then begins within a day to decline until the temperature is normal and the constitutional symptoms have almost disappeared The whole febrile phase lasts about three weeks After a day or so of normal temperature fever recurs with exacerbation of the other constitutional symptoms There may be only two such waves or they may recur for a period exceeding a year The average length of an attack of the undulant type is about three months

The undulant type results not only from infection with the caprine strain of *Brucella* as seen in the Island of Malta and in the Pecos Valley of Texas but also with the porcine and bovine strains now being observed all over the United States There is great variability among the caprine cases but in general the bovine strain seems to produce a milder type of infection than either the caprine or the porcine The great majority of cases in the United States are of porcine origin, with the remainder bovine Caprine infection in this country is rarely observed except in Texas and Arizona

About 15 per cent of the cases in the United States are of the undulant type In general the first wave of the undulant type is like an attack of influenza while in the second wave there is intensification of symptoms with headache constipation and insomnia Sweating may be present in the first wave but usually does not appear until the second wave Stitt in contrasting the infection of caprine origin with the cases of porcine and bovine source as seen in the United States notes the following outstanding features in the latter group remarkable absence of physical signs (including infrequent splenomegaly), profuse redolent sweating loss of body weight fatigability with absence of prostration joint manifestations and neuralgias not so common or severe abdominal pains more prominent even

devoted to the mental depression which accompanies the infection

Specific treatment is not yet on a firm basis The sulfonamides have been used with apparently good results in a few cases but on further trial have been disappointing

In acute cases with low agglutinin titer Foshay's goat or horse antiserum is given intravenously or subcutaneously after testing for sensitivity in 20 cc doses daily for five days or until there is evident improvement The average amount of serum given is from 90 to 120 cc Serum therapy is not advised after the eighth month of the disease As the response to serum treatment is uncertain the possibility of added discomfort by serum sickness must be taken into account

In prolonged cases frequent small transfusions of 250 cc by the indirect method are advised The use of donors who have been immunized against brucella is a logical procedure

Vaccines may be given in the chronic or recurring type especially when the agglutinin titer of the patient's serum is low Systemic reactions may be severe It is well to begin with 0 1 cc of a 1 100 dilution of the vaccine and increase the dose guardedly and according to the severity of the reaction The vaccine is given intracutaneously at five-day intervals

Brucellin the nucleoproteins of the organism in a mildly alkaline solution has been used successfully by Huddleson It may be used with care in selected cases Some patients have marked constitutional reactions to small doses while others may be given as much as 1 cc without discomfort The positive skin test with brucellin denotes sensitivity to the nucleoproteins In cases in which the agglutinins and cytophagic index are high and the skin test with brucellin is markedly positive the patient should be desensitized by graduated injections of brucellin The series of injections begins with 0 1 cc intracutaneously and is repeated at five day intervals increasing the amount by 0 1 or 0.2 cc until 1 0 cc is given A dilution of 1 10 is then employed in like manner

In cases of long duration search should be made for localization especially in the gall bladder or prostate If treatment with sulfapyridine combined with daily diathermy through the site of the localization is not effective surgical excision is indicated

Harold L Amoss

PERTUSSIS

(*Whooping Cough French coqueluche German Keuchhusten Italian pertosse Spanish tos ferina*)

Definition—Pertussis is an acute infectious disease of the respiratory tract characterized in its typical form by a series of repeated spasmodic coughs followed by a sudden forceful inspiration (the whoop) and sometimes by vomiting Since the disease may exist without the whoop and since other infections of the respiratory tract may be associated with this symptom the name pertussis is preferred to that of whooping cough

Historical—Although the earliest reference to the disease was probably made by Moulton in 1540 De-Baillou in 1578 is credited with the first classical description of pertussis As quoted by Major DeBaillou discussed the disease in part, as follows "Principally that common cough which is usually called Quinta or Quintana which has been mentioned before Serious are the symptoms of this The lung is so irritated so that every attempt to expell that which is causing trouble it neither admits the air nor again easily expels it The patient is seen to swell up and as if strangled holds his breath tightly in the middle of his throat." "For they are without this troublesome coughing for the space of four or five hours at a time then this paroxysm of coughing returns now so severe that blood is expelled with force through the nose and through the mouth Most frequently an upset of the stomach follows nor have I read any author who has made mention of this cough

Incidence—Pertussis is sporadic and endemic to the more thickly populated communities throughout the world Epidemics

After the first week agglutinins may be present, but often they are not found at all, or not until late in convalescence If agglutinins are not demonstrable in a suspected case, a skin test with 0 05 cc of 1 500, or 0 1 cc of 1 1000 solution of *brucellergin* read after forty eight hours will often prove valuable A positive reaction indicates present or past infections with *Brucella* and denotes a hypersensitive state to the nucleoproteins of this organism To determine whether the positive skin test results from active or inactive *Brucella* infection the phagocytic test of Huddleson is necessary A positive phagocytic reaction is found in the immune, or inactive state a negative reaction in the presence of a positive skin test denotes active infection

At the present time, with typhoid fever on the wane and increasing incidence of brucella infection, the clinician should be mindful of the latter disease in any case of fever of unknown origin

Differential Diagnosis—There are no pathognomonic signs in brucella infection The acute onset is usually more gradual than in *typhoid fever* and the effect on the sensorium less marked The fastigium is usually very brief and the abdominal signs and symptoms are mild In both diseases there is prostration but in brucellosis the sweating is usually pronounced especially in the second wave while it is absent in typhoid fever The usefulness of cultures in differentiating these diseases is obvious Commonly there is a definite leukopenia which suggests either typhoid or *influenza* The differential diagnosis between brucellosis and influenza is sometimes difficult because of the prostration and general aching sweating and leukopenia in both diseases Influenza is of shorter duration more abrupt in onset and there are usually evidences of upper respiratory infection The typhoidal type of *tularemia* with absence of clinical signs may simulate brucellosis especially if cross agglutination is reported as sometimes happens The insidious onset in some cases with weakness loss of weight, anorexia sweating and low white count suggests *tuberculosis*

Brucellosis may be confused with *malaria rheumatic fever* and *pyogenic infections* but appropriate observation and study differentiate them

On account of the abdominal pain and tenderness cases of brucellosis have been diagnosed as *acute appendicitis* or *cholecystitis* and operated upon Brucellosis of long duration, with gradual onset fever loss of weight, anemia, hematuria joint pains splenomegaly and even petechiae may be justifiably diagnosed as *subacute bacterial endocarditis* The differentiation is made by blood cultures and skin tests Occasionally the occurrence of orchitis and vesiculitis in brucellosis leads to suspicion of gonorrheal infection

Long enduring cases with nervousness weakness and depression have been mistaken for *neurasthenia*

Prognosis—The mortality rate in undulant fever is from 2 to 3 per cent Infection with the bovine type is usually milder than the porcine infection The average duration is three to four months In about 20 per cent of cases the patient is able to return to work within one month In 25 per cent the period is from one to two months in 35 per cent three to four months in 12 per cent from five to six months and in 8 per cent the period is from six months to two or three years The writer has reported 1 case of incapacity for eight years with ultimate restitution

Prophylaxis—Pasteurization will prevent the cases arising from raw milk Measures for the control of contagious abortion in cattle are reducing the danger from milk but the other great problem of infected hogs has not received attention Apparently the organism penetrates the skin making prevention difficult for veterinarians and abattoir employees Long rubber gloves should be worn by the former when caring for cases of abortion Vaccination with several antigens of the porcine group should be tried on a large scale among slaughterhouse employees Laboratory workers should be vaccinated with several antigens before handling brucella cultures

Treatment—The general measures advocated in the treatment of acute infections are applicable in brucellosis rest in bed forcing fluids alcohol sponges and ice caps as indicated Mild sedatives such as phenobarbital are often necessary and aspirin but not amidopyrine is helpful for aches and joint pains Especial attention should be

Large amounts of thick ropy mucoid material are coughed up swallowed or vomited Perspiration congestion of the neck and scalp veins mental confusion and exhaustion may follow the more severe paroxysms Infants particularly may become so cyanotic and exhausted that they may require artificial respiration

Excitement sudden thermal changes swallowing inhalation of irritating fumes tobacco smoke or even the occurrence of a paroxysm in a nearby patient may excite a spell of coughing If a plug of mucus remains in contact with the hyperesthetic mucous membrane of the respiratory tract recurrent paroxysms very likely follow until it is dislodged Epistaxis often occurs when the spasms are severe Subconjunctival hemorrhages and edema of the lower eyelids occur frequently in cases with severe coughing

Convalescent Stage—The number and severity of the paroxysms gradually decrease vomiting becomes less frequent and the disease thus progresses into the stage of decline or convalescence During this period the hilar and basilar rhonchi gradually disappear For a period of weeks or months an intercurrent infection may cause the major symptoms to reappear even to the point of resembling a new attack

It must be remembered that pertussis is a variable disease and may exist in a very mild atypical form The entire course may last only a few days Proved cases have been known to last but from seven to fourteen days Vomiting and the classical whoop may never occur Very young infants particularly may have choking and cyanotic spells without the whoop

Complications and Sequelae—Bronchopneumonia is by far the most important complication This is usually interstitial in type Lobar pneumonia is rarely seen but occasionally confluent bronchopneumonia produces a lesion which clinically resembles that seen in the lobar type Atelectasis is common due to the blocking of a bronchus with mucus resulting in collapse of a portion of the lung and frequently leading to the erroneous diagnosis of pneumonia Vesicular and interstitial emphysema occurs in practically all severe cases Emphysema of the cellular tissue of the mediastinum may result from rupture of air blebs on the surface of the lung From the mediastinum the air may find its way into the subcutaneous tissues of the neck and even spread to other portions of the body Cases with widespread subcutaneous emphysema are usually fatal In one case of this type which later came to anatomic examination there was hyperleukocytosis of 257 000 Pneumothorax may occur Bronchial asthma and bronchiectasis may result from an attack of pertussis An existing tuberculous lesion may spread during the disease although the effect of pertussis on tuberculosis is probably not as disastrous as was formerly believed Unresolved pneumonia and pulmonary fibrosis are of common occurrence Cardiac dilatation particularly of the right side is observed It is most commonly associated with diffuse pneumonic involvement

Otitis media is frequently encountered and is due to secondary invading organisms Because of the tendency to suppurate the ears require the careful attention of the attending physician

The hemorrhages of pertussis are mechanical in origin resulting from the venous congestion associated with severe coughing Epistaxis and hemorrhage of the bulbar conjunctivae are common Blood tinged sputum is a result of small erosive lesions in the trachea which occur during a paroxysm Hemorrhage of the brain has been reported

The most common neurologic complication of pertussis is convulsions They occur in about 8 per cent of hospitalized cases and are especially common in infants The spinal fluid of those suffering from convulsions is usually normal

Other neurologic complications of pertussis are Epilepsy mental retardation spastic paralysis myelitis and temporary or permanent visual disturbances

Hernia usually umbilical and prolapse of the rectum are results of severe straining associated with the cough Ulcer of the frenum occasionally results when the tongue is repeatedly thrust over the edge of the lower incisor teeth during the paroxysms

Diagnosis—Typical pertussis in the paroxysmal stage can be readily recognized In the catarrhal period and in the atypical abortive form it is difficult to diagnose Pertussis should be suspected in an individual

prevail at intervals of two to four years While cases occur regularly during the summer months, they are more numerous in winter and spring, when complications are likewise more frequent The peak of the incidence in the southern states occurs in May in the North in January or February It appears to be more frequent among females The communicability rate is high resembling that of measles and varicella In family exposures it approximates 85 per cent

Although pertussis occurs at all ages it is decidedly a disease of early life About 85 per cent of all cases occurs in individuals less than seven years of age and about one half of these is found in infants less than two years of age While maternal immunity may be passively conferred upon the newborn in certain instances infants younger than six months of age are very susceptible and are subject to a high mortality

Etiology —*Hemophilus pertussis* discovered by Bordet in 1906 is now considered to be the cause of pertussis for the following reasons

1 The organism is found in the upper respiratory tract during the early stage of the disease but not during recovery

2 The organism is seldom found in normal persons or in those suffering from other types of respiratory infection

3 The disease can be reproduced experimentally by inoculation of the upper respiratory tract of a suitable animal or man with pure cultures of *H pertussis*

4 Specific humoral antibodies may be demonstrated during the course of the disease and after active immunization

Although evidence exists that a filtrable agent may act as a dual etiological factor in the disease it is safe to say that an associated virus is not essential in the reproduction of the experimental disease

Certain other organisms are capable of producing infections of the respiratory tract that closely resemble that produced by *H pertussis* Among these are *Hemophilus influenzae* *Brucella bronchiseptica* and *Bacillus parapertussis* The last two of these probably share common antigen components with *H pertussis*

Pathology —Catarrhal infection of the epithelium of the larynx trachea and bronchi is always present Numerous clumps of *H pertussis* may be demonstrated here The essential lesion probably consists of necrosis of the midzonal and basal portions of the bronchial epithelium with infiltration of this area by polymorphonuclear leukocytes Peribronchiolitis extending from the hilum along the bronchial vascular rays to the middle or even the outer zones of the lung occurs As the lesion progresses typical interstitial pneumonia develops Edema and hemorrhage mark the early stage of parenchymal involvement Accumulation of mucus pus and cellular debris within the alveolar spaces results chiefly from infection by secondary invading organisms It is probable that *H pertussis* is responsible for the lung lesion to a considerable degree

In cases characterized by severe paroxysms or convulsions the brain is intensely congested and may reveal punctate or even large hemorrhages In rare instances encephalitis with degeneration and atrophy of the cortex has been described

Symptoms —The incubation period though variable is usually from seven to fourteen days In a series of 1123 cases Lawson found the mean duration of the period to be thirteen days The course of the typical disease is six weeks in length representing three stages The catarrhal spasmodic and convalescent each lasting approximately two weeks

Catarrhal Stage —This period begins with a mild cough usually nocturnal which progresses in intensity and soon becomes diurnal The mean duration of this period according to Lawson is eleven days Coryza and sneezing are usually present and the appetite fails The cough later resembles that of bronchitis At this stage the physician is frequently consulted In rare instances hoarseness is present and occasionally the disease begins with the features of acute obstructive laryngitis There is often suffusion of the conjunctivae

Spasmodic Stage —After about ten to fourteen days the cough becomes so aggravated that it occurs in series of explosive efforts in which the face becomes congested often cyanotic the tongue protrudes with each cough and the patient appears to strangle Finally the attack ends with a sudden forceful inspiratory crow or whoop

is one of the most fatal The younger the patient the more grave is the prognosis About 60 per cent of the deaths occur during the first year of life In infants under one year the mortality is about 25 per cent during the second year it is about 10 per cent over five years of age the disease is seldom fatal During a period of thirteen years from 1926 to 1939 the mortality rate at the Rochester Municipal Hospital for infants under six months was 30 per cent The Report of U S Public Health Service for the year 1937 recorded 214 652 cases of pertussis from 48 states and the District of Columbia with 4929 deaths a fatality rate of 2 3 per cent In surveyed communities however Sydenstricker and Wheeler have reported the extremely low fatality rate of 0.36 per cent

Prevention—Young infants particularly the debilitated and those with positive tuberculin reactions should be carefully protected from exposure The period of infectivity is about six weeks although the most infective stage is the catarrhal Rigid isolation not only protects others but it shields the patient against superimposed respiratory infections Specific active prophylaxis should be carried out between the ages of six and twelve months The initial course of vaccine should total from fifty to eighty billion organisms The exposed infant should be given immune adult serum hyperimmune human serum or convalescent serum The dosage of these serums should be from 10 to 40 cc injected intramuscularly

Treatment —*General Measures*—Rest in bed is highly desirable Fresh air and sunshine are important but extreme changes of temperature stimulate coughing A range of from 65° to 75° F has been found satisfactory Frequent small feedings are better than large meals If a feeding is lost by vomiting it is well to refeed When abdominal distention is present milk should be temporarily withheld from the diet The use of a snug abdominal support may help If cyanosis is present oxygen is definitely indicated Careful use of suction has been found beneficial in some cases where excessive mucus obstructs the respiratory tract A roentgenograph of the lungs and a cutaneous tuberculin test are recommended during convalescence

Medication—Nearly all sedatives will aid in decreasing the number of coughing spells and help to assure rest and sleep Codeine, paregoric and phenobarbital are commonly used Sodium bromide and antipyrin constitute a useful combination The instillation of a mixture of 2 to 8 cc of ether in 15 cc of olive oil rectally is beneficial if the paroxysms are severe Oversedation is distinctly harmful and causes the patient to retain excessive amounts of mucus in the lower respiratory tract Regan and Tolstoouhov recommended alkalization therapy on the theory that the disease is characterized by a state of uncompensated acidosis

Fig 23—Roentgenograph showing typical bronchopneumonia in a fatal case of pertussis S R., #166171 female 4 weeks of age Third week of pertussis WBC 50 000 Anatomical diagnosis (A—6041) Bronchopneumonia bilateral Bronchitis Pulmonary atelectasis bilateral Bacteriology· Naso-pharyngeal culture H pertussis Hemolytic streptococcus Lungs (Post mortem) *H pertussis*

Specific Therapy—There is at present no evidence that vaccine or other types of antigenic substances possess therapeutic value unless the patient has been previously actively immunized in which case the injection of vaccine during the catarrhal period is indicated

It is important to culture the nasopharynx for secondary invading organisms particularly if pneumonia exists To such cases sulfadiazine 0 1 Gm (1 5 grains) per kg (2 2 lbs) of body weight per 24 hours should be given There is recent evidence that sulfadiazine is also effective against *H*

suffering from a cough of a week s duration if examination of the nose, throat and chest reveals no apparent cause for it History of exposure may not be elicited The physician may be obliged to defer diagnosis until the cough becomes more definite In such instances the patient should be isolated and a culture taken if the facilities are available In doubtful cases inquiry should be made concerning previous injections of vaccine since mild atypical cases may occur as a result of the partial immunity thus conferred

Pathologic Physiology —The essential departures from the normal physiologic state observed in pertussis are (1) those related to disturbances in nutrition (2) those resulting from changes in the pulmonic circulatory system and (3) those referable to the central nervous system

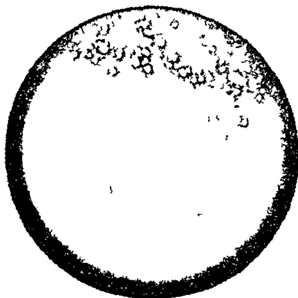

Fig 22 —Photograph of a 72 hour growth of *H pertussis* on Bordet medium Practically pure culture isolated by naso-pharyngeal method

Loss of appetite and vomiting cause weight loss Excessive vomiting may produce gastric tetany In infants diarrhea frequently occurs Dehydration starvation and emaciation impair nutrition to the extent that fatal secondary infections develop

Irritation of the mucous membranes of the trachea and bronchi provokes the paroxysm Obstruction of the lower air passages by mucous plugs induces atelectasis which along with interstitial pneumonia prevents proper oxygenation of the blood According to Regan and Tolstoouhov a state of uncompensated acidosis results Enlargement of the right side of the heart may result from increased impediment of the pulmonary circulation

Anoxemia probably causes convulsions in many instances Infancy, pneumonia and severity of the paroxysms are important factors Cerebral congestion edema, hemorrhage and encephalitis are responsible for convulsive and other types of disturbances in the central nervous system In rachitic infants, convulsions may be due to tetany

The most valuable of the laboratory diagnostic tests consists in the isolation of the organism from the upper respiratory tract This may be accomplished by the cough plate technic or by the nasal swab method Bacteriological diagnosis is particularly applicable during the catarrhal period when positive cultures may be expected in from 70 to 90 per cent of the cases Only positive cultures are significant A single negative culture does not rule out the disease

A characteristic change in the white blood cells occurs during the late catarrhal or early spasmodic stage This consists in a definite leukocytosis of from 15 000 to 40 000 white blood cells per cubic millimeter reflecting progressive increase in the absolute number of lymphocytes Occasionally extreme degrees of hyperleukocytosis occur usually in cases complicated by pneumonia This change in the leukocytes is probably due to direct stimulation of the hematopoietic tissues by *H pertussis* Failure to find this blood change does not constitute conclusive evidence against the existence of the disease

In certain instances the finding of a significant titer of humoral antibodies in an unvaccinated patient may suggest recent infection with *H pertussis* Tests for agglutinins complement fixing and mouse protective antibodies may be made with the patient s serum Unfortunately humoral antibodies do not appear until the paroxysmal stage hence they are of little diagnostic value early in the disease

Attempts to develop a diagnostic skin reaction with various toxins and fractions of the organism have not been entirely successful

Prognosis —In older children pertussis may be a relatively mild disease in infants it

caused by *Pfeifferella whitmori* produces a Straus reaction Although primarily a disease of rodents (rats) in Rangoon Ceylon the Netherland Indies and Indo China at least ninety eight human infections of melioidosis have been reported since 1912 The possibility exists that the causative organism may be found in other parts of the world *Pf whitmori* differs from *Pf mallei* in the following particulars it is motile, forms a corrugated growth attacks a larger range of carbohydrates and decomposes sodium fumarate

Epidemiology —*Equine animals*—In the United States and Canada glanders was quite prevalent until 1905 suppressive measures have almost freed these countries from the disease Complete eradication has been accomplished in Canada and only occasional cases have been disclosed for a good many years in the United States During the World War Germany had to destroy 5776 and France diagnosed 58 843 glanders infections in horses of which 294 died of the disease and 20 585 were slaughtered It is still prevalent in the Balkans (9856 cases in Rumania 1938) and in Russia where as many as 2 to 4 per cent of horses are infected Glanders as a disease of horses mules and donkeys appears in two clinical forms—acute (mules and asses) or chronic glanders of the lung and glanders of the skin and regional lymphatics (farcy) According to Eberbeck who dissected 305 horses the lungs were diseased in 99 67 per cent the region of the nose in 61 9 per cent and the skin in 13 1 per cent of the cases The course of the infection is frequently occult or latent and is recognized only when a mucoid nasal discharge with enlargement of the submaxillary lymph nodes and ulcers in the skin makes its appearance Experience has taught that glanders is spread among equines by water supplies *e g* drinking troughs which have become soiled with the nasal discharge containing the *Pfeifferella mallei* in great numbers Since the bacilli are also excreted from the skin and mouth such objects as feed bags harness brushing and grooming utensils even bedding and fodder liable to contamination with such excretions are especially dangerous By eating of the flesh of glandered horses cats may become infected

Man—Today glanders in man is rare In the Philippines 4 human cases of glanders were seen in 1933 while in the United States 1 case was placed on record in July, 1939 The Bureau of Census records one or two deaths per year The malady affects preeminently those who have intimate relationship with horses suffering from chronic glanders As an occupational infection it is seen in grooms coachmen veterinary surgeons soldiers farmers etc Several cases have been reported in laboratory workers indeed probably no organism with the exception of *Bacterium tularense* is so dangerous to work with as glanders Man to man infections have doubtless been observed in a few instances Infection results most frequently from contamination of an abrasion or wound with glanderous discharge but primary invasion of the conjunctiva and possibly the respiratory and alimentary tract may occur Small epidemics among soldiers and children due to the ingestion of flesh from fallen or killed glandered horses have been reported from Russia

Symptoms —Just as in the horse glanders manifests itself in man in an acute and chronic from In this connection it should be emphasized that chronic glanders frequently may terminate with acute symptoms and in rare instances a case with typical acute onset may run a chronic course

Acute glanders is one of the most dreaded skin infections of man After an incubation time of from a few hours to three weeks on the average four days general malaise anorexia chills fever up to 104° F vomiting diarrhea and rheumatic pains accompany the local swelling and infiltration at the site of the cutaneous infection Ulcers with irregular edges and sloughing yellow grayish bases appear and multiple intramuscular and subcutaneous nodules along the lymphatics the so called farcy buds are gradually transformed into abscesses The skin over these nodes ulcerates the lesions spread rapidly and coalesce into painful serpiginous ulcers with deep sinuses discharging a pink reddish to grayish pus They show little tendency to heal When the infective agent localizes on the mucous membranes (about one third of the acute cases) a papular or pustular eruption precedes the ulcerations When the primary lesions are in the

pertussis Blood transfusions from adult immune donors and the intramuscular injection of 20 to 40 cc of convalescent serum are of therapeutic value *Blood serum obtained* from adults hyperimmunized with pertussis vaccine increases the specific humoral antibodies of the patient when injected intramuscularly in amounts of 20 to 40 cc and constitutes a beneficial form of specific therapy particularly in small infants

If pneumonia exists, it is important to culture the sputum If pneumococci or hemolytic streptococci are present sulfadiazine should be administered

GLANDERS

(Farcy Morve Rotz Malleus Hautwurm)

Definition—Glanders an infectious disease of equines (horses mules and donkeys) occasionally transmitted to man is caused by a specific micro organism *Pfeifferella mallei* The infection is characterized by the formation of nodular lesions in the internal organs and by ulcerative papules or nodes of the skin and subcutaneous tissues and of the respiratory mucous membrane

History—In ancient times certain diseases of the equine species were known as μηλις Its transmissibility was proved in the eighteenth century its microbic nature was recognized by Chavuveau in 1868 and the *identification of the organism was fully* established by Loffler and Schutz in 1882 and 1886 They isolated the *Bacillus mallei* in pure culture and produced with these cultures typical glanders in horses As a diagnostic agents mallein was produced by Helman in 1891 serological methods were developed by Schnurer (1905) *and the complement* fixation test by Schutz and Schubert (1909)

Etiology—In smears prepared from the viscid pus of the abscesses *Pfeifferella mallei* is seen in extracellular or intracellular location usually in small numbers as straight or slightly curved rods with rounded ends 1.5 to 3.0 microns long and 0.5 micron broad single *sometimes arranged in pairs or* parallel bundles It is nonmotile noncapsulated and gram negative, stains distinctly with alkaline methylene blue or carbolthionin exhibiting a characteristic beaded granular or bipolar appearance The organism produces on all the common culture media under aerobic conditions a slimy growth which has a tendency to develop a brownish coloration with age Particularly on potato media, this pigmentation is readily demonstrable For primary isolation horse serum or potato agar media should be heavily sown with infective material

Since other micro organisms which resemble the glanders bacillus have been described it is advisable to test the pathogenicity of the isolated bacteria on male guinea pigs Following intraperitoneal or even subcutaneous injection the organism localizes in the serosa covering the tunica vaginalis and incites a thick purulent exudate The testes are swollen (second to *twelfth day) and the scrotal skin may* become adherent and ulcerated the animal usually dies between the tenth and the fourteenth day This testicular reaction first described by I Straus (1889) is diagnostically significant provided the exudate *is* controlled both microscopically and culturally Several different species of bacteria (*B pyocyaneus B preisz nocard Brucella* etc) and fungi (*Sporotrichum Coccidiomyces* and others) produce a Straus reaction similar to that induced by *Pfeifferella mallei* Of particular importance is the fact that the organism of *melioidosis* a disease of man which resembles glanders very closely and is

ease is diagnosed Very few cases ever recover On the other hand the curability of chronic glanders is recognized and according to various authorities from 30 to 50 per cent survive independently of treatment

Treatment—The patient must be isolated and the discharges carefully disinfected Aside from symptomatic treatment and complete rest most of those who have had experience with glanders are convinced that drugs have no effect on the disease Prompt and radical surgical measures are the most reliable means of treating the chronic disease Vaccine therapy has been tried with some success in a few cases (Gaiger Zieler and O Fischer) Chemotherapy with diverse preparations (mercurial inunctions copper derivatives and arsenicals) has yielded no success

Prevention—The prevention of glanders in man depends on the vigorous suppression and ultimate eradication of the disease in horses Until accurate diagnostic methods had been worked out the control of glanders was difficult since mild abortive and latent glanders are common and important factors in the spread of the infection in the crowded parts of cities With the aid of the mallein test—intradermal palpebral and ophthalmic—and the agglutination complement fixation and conglutination tests horses in infected or suspected stables are now accurately examined All animals proved to be infected with the disease whether in the clinical or latent form must be destroyed and properly disposed of and the stable and objects exposed to contamination thoroughly cleansed and disinfected with bleaching powder preparations Horses which have been in contact with infected animals although considered healthy by allergic and serologic tests must be reexamined every three weeks Should there be no indication of the disease in these tests the stable may be considered free from glanders The education of persons who handle horses should call attention to the importance of rubber gloves thorough disinfections and other methods of protection Special care should be taken to prevent the spread of the disease through the discharges and contaminated fomites from human cases Cultures of *Pfeifferella mallei* and laboratory tests with the organism are dangerous and should not be entrusted to beginners

ANTHRAX

(Charbon Maladie Charbonneuse Milzbrand Malignant Pustule or Cutaneous Anthrax Woolsorters Disease Rag Pickers Disease or Pulmonary Anthrax)

Definition.—An acute infectious disease—caused by the *Bacillus anthracis*—which attacks many species of animals in particular herbivora and is transmissible from them to man Clinically it takes the form of an external (malignant pustule and malignant edema) or internal (pulmonary and rarely intestinal) disease

Historical—Anthrax as a disease has been known from antiquity the name is derived from the Latin *Anthrax* a carbuncle Maret (1752) and Fournier (1768) defined the clinical type of malignant pustule in man while Chabert (1780) described anthrax in animals and Barthelémy (1823) proved its transmissibility by inoculation Subsequently Davaine (1863–1864) showed that anthrax was caused by a living organism that multiplied in the body invaded the blood stream and produced death by septicemia He found the same organism in the malignant pustule and thus demonstrated the etiologic identity of the disease in man and animals The final proof of the causative role of *Bacillus anthracis* was furnished by R Koch (1877) in his classic monograph when he described the formation of spores the cultivation of the organism in vitro the reproduction of the disease by injection of pure cultures and the recovery of the bacillus at autopsy Thus the study of anthrax established for the first time the specific relationship of a microbe to an infectious disease

Etiology.—The *Bacillus anthracis* so designated by Ferdinand Cohn (1875) and by many claimed as the corner stone in modern bacteriology in a non motile gram positive rod which forms capsules in the tissues of man and animals and sometimes

nose the sticky blood tinged secretion gradually becomes converted into ropy, viscid mucopus and excoriates the skin over which it runs, forming crusts on the lips and mouth Sometimes the disease commences with symptoms suggesting influenza, pneumonia or typhoid fever, one is then struck by the degree of prostration, which is entirely out of proportion to the clinical signs With the development of localized purulent foci a bacteriologic examination may establish the exact nature of the infection An *exanthematic eruption* in the form of brawny, purplish lentil shaped spots and pustules containing clear yellow white matter, which appear on the face neck, trunk and limbs is indicative of sepsis and is the precursor to death Invariably the glanders bacillus may be isolated in blood cultures Delirium and coma precede the fatal termination which may occur within one to seven weeks, due to circulatory collapse

Chronic glanders may at first show negligible constitutional symptoms, fever may be absent although general malaise inertia and pains in the extremities are comparatively common Within one to four weeks however an irregular fever develops which tends to assume a septic character with deep remissions The most constant lesions make their appearance in the form of subcutaneous or intramuscular abscesses or tumors on the upper and lower extremities on the head and neck, rarely on the trunk as a rule the regional lymph nodes are enlarged The earlier lesions are usually very painful and tender, they may rapidly ulcerate or on incision suppurate profusely, discharging specific organisms in small numbers Stubborn resistance to treatment and partial healing with discharging sinuses and a tendency to spread are striking features of the disease Involvement of the joints and periosteum of the bones is not rare Pulmonary and pleural disturbances in the form of bronchitis consolidation and exudates are reported in about one quarter of the cases Some cases present only the symptoms of a minor ailment but lose rapidly in weight and strength Emaciation usually accompanies the development of foci Periods of irregular fever and profuse sweating may be followed by quiescent intervals during which the patient may regain his strength

This peculiar remittent type of disease may drag on for years the average duration from a minimum of six weeks to a maximum of fifteen years is about one and one half years Remissions at intervals of from two to five years have been observed The lesions may heal slowly, or a remission with rapid generalization resembling acute glanders may lead to a fatal termination Many cases succumb to cachexia and amyloid disease Chronic glanders may be latent at the beginning and during the entire course of the disease A personal account of chronic relapsing glanders in a veterinarian gives a vivid description of this distressing malady (Gaiger)

Diagnosis—The varied clinical picture renders the diagnosis difficult However, any wound infection in a person with a history of contact with glandered horses or with laboratory handling of *Pfeifferella mallei* should be regarded as gravely suspicious and proper bacteriologic tests by culture and animal inoculation should be instituted Aside from the bacteriological tests the *newer serologic procedures* are indispensable The most trustworthy reactions have been obtained with the complement fixation test the technic is the same as that used in the recognition of latent equine glanders As a rule the serum of a patient with glanders fixes complement in a dilution of 0 1 to 0 05 cc Agglutination reactions in dilutions of 1 800 are diagnostic In chronic glanders the antibodies persist for a long time but certain fluctuations in titer have been observed It is therefore advisable to employ several methods of examination (complement fixation agglutination and conglutination) and to make repeated tests The allergic tests with mallein are rarely used although the ophthalmic and cutaneous tests are always positive in glandered human beings In fact the injection of dead *Pfeifferella mallei* for therapeutic purposes induces both local and general reactions The glanders like disease *melioidosis* described by Stanton and Fletscher is not readily diagnosed or differentiated from glanders during life At autopsy the causative organism can be readily isolated from the visceral lesions

Prognosis—The gravest prognosis must be rendered when the acute form of the dis

to 3 per cent) have occasionally been recorded the disease may take the form of anthrax meningitis The carelessness or indifference of manufacturers in using Chinese Indian or Siberian horsehair due to upsetting of the usual trade routes was largely responsible for these infections

The second type which may take the form of cutaneous anthrax or of pulmonary disease is dependent on an infection acquired during the treatment of animal products It shows no seasonal incidence Of the 262 cases reported in the United States between 1934 and 1938 skins hides and tanneries were responsible for 93 wool 38 hair and furs 18 while 89 occurred among agricultural workers (Henry Field Smyth 1939 Sixth Report of the Committee on Anthrax) The products—hides and hair—soiled with blood invariably come from regions where the disease in common in animals and the civilization low Pulmonary infection was commoner than malignant pustule fifty years ago but thanks to improvement in industrial hygiene legislation and the introduction of exhaust ventilation dust masks proper clothing etc this type is now infrequently seen and reported

The statistical data collected by the United States Public Health Service and supplemented by the analyses made by Henry F Smyth are listed below and indicate that approximately 60 to 80 cases of anthrax with a case fatality rate of from 17 to 22 per cent are recognized annually in the United States (principally Pennsylvania New York Massachusetts and Texas)

Years	Cases	Deaths
1919–1923	461	107 (23%)
1924–1928	468	100 (20%)
1929–1933	379	85 (22%)
1934–1938	375	61 (16%)

The infection chain—animal man—is invariably broken no instance is known in which the disease was conveyed from man to man although a healthy person may be a carrier (passive porter) as regards spores in his clothing

Symptomatology —(*A*) *External Anthrax* —1 MALIGNANT PUSTULE —The most common form (95 per cent) of cutaneous anthrax is seen by the physician when the carbuncle has already developed From one to three days after the infection the reddened area of the skin on the arm neck or face shows a fleabite like patch which is transformed into a painless and insensible papule Intense itching accompanies this primary lesion in its evolution to a vesicle with a hard dark purplish black center It is of interest to note that the site of the lesions varies with the nature of the industry Hide porters are frequently infected on the back of the neck which is more open than other parts to excoriation In the case of butchers and veterinarians who handle carcasses the arms or hands are affected As a rule only one focus is present although the scratching may lead to auto-infection and the formation of several papules and multiple vesiculation with yellowish or hemorrhagic or even purulent content Within a few hours after the appearance of the papules the soft tissues in the immediate vicinity become infiltrated and swollen Coagulation necrosis desiccation or scratching by the patient produces a dark bluish red tough leathery eschar which extends both with regards to depth and width and forms with the densely edematous ring studded with small vesicles the characteristic carbuncle The term pustule is unfortunate for pus formation is absent The massive infiltration joins an extensive hemorrhagic edema which may extend along the neck to the face or chest or even to the abdomen and lead to extraordinary distortion of the involved parts Reddened lymphatics spread from the carbuncle to the regional lymph nodes which are painful swollen and sometimes covered by an area of reddened and inflamed skin In the mildest form with but little swelling the primary papule vesiculates rapidly and the resulting scab separates in a few days Recovery in the more severe cases is indicated by the gradually sloughing suppuration of the eschar at the end of the first week recession of the edema and slow healing of the extensive defect by granulation leaving a disfiguring scar

Quite early general symptoms in the form of headache joint pains nausea malaise and fever may accompany the evolution of the carbuncle The temperature varies in the majority of cases it is elevated on occasions it may be normal or even subnormal The count of the white blood cells may show a slight increase (10 000–13 000) or a

on artificial media, grows on agar in characteristically long (up to 10 microns), segmented parallel or interwoven chains Under conditions of unfavorable growth outside the body it forms ellipsoidal or oval spores which are quite resistant to heat (ten minutes boiling) and to chemical disinfectants like $HgCl_2$ which they resist for seventy hours in concentrations of 1 1000, but are readily destroyed with agents acting by oxidation Potassium permanganate in 4 per cent solution kills in fifteen minutes or hydrogen peroxide in one hour The capsule consisting of a glycoprotein is definitely correlated with the pathogenicity of the bacillus for a diversity of animals besides the herbivora and man Infections of guinea pigs and mice may best be achieved by the intramuscular route of relatively large doses of bacilli In culture the organism produces *toxic albumoses* largely disintegration products of proteins in the media When freshly isolated from the animal body, the anthrax bacillus rarely causes difficulty in identification The capsule formation the inverted fir tree growth in gelatin stab and the pathogenicity for guinea pigs distinguish the microbe from those of anthrax like or pseudo-anthrax bacilli (*B subtilis* and *B megatherium*)

Epidemiology—As a disease of *animals* with a worldwide distribution anthrax has been known for centuries The character of the infection chain is fairly clear and it is fully established that man contracts anthrax secondarily through direct or indirect contact with animals or animal products Rarely is anthrax spread from animal to animal, infection occurs primarily and secondarily by the alimentary tract from feeding on contaminated pasture in lowlying marshy areas stagnant pools or banks of rivers where in warm countries the bacillus may grow during the summer months In cold countries the sources of infection are artificial food stuffs such as bone blood fish maize meal and oil cake A mechanical transmission by biting flies occurs infrequently Anthrax in animals (cattle, horses sheep goats buffaloes elephants and minks) takes the form of a septicemia varying from an acute apoplectic attack to a subacute disease accompanied by intestinal disturbances local cutaneous swellings and a mortality of from 75 to 100 per cent In dogs cats, and swine the disease results from feeding on the carcasses of infected cattle the localization is principally in the larynx and pharynx and may be mild or latent The bacilli in the blood or discharges are in the vegetative stage but rapidly sporulate when exposed to suitable temperatures and oxygen These spores are very resistant Multiplication in the soil depends on the hydrometeorologic condition they remain viable in the soil for over fifteen years (Pasteur)

Distribution and Incidence—Anthrax infection is known to exist in a few fairly well defined districts in the United States these are (1) southeastern South Dakota and northeastern Nebraska, (2) the delta regions of the lower Mississippi Valley and (3) a belt along the Texas gulf coast In these districts occasional serious outbreaks occur but the incidence is kept down by appropriate preventive measures

Anthrax in man may be conveniently divided into (1) the *nonindustrial type* (11 16 per cent), affecting farmers butchers sheepherders veterinarians and others who come in close contact with diseased or fallen animals or insect bites and (2) the *industrial type* arising from the handling of hides and skins (37–46 per cent) or wool animal hair and bristles (28–34 per cent) and occurring in the hide tanning and leather industries brush and broom making horse-hair factories furriers and taxidermists rag sorting horn and grain porterage The susceptibility of man to anthrax is relatively low and individually quite variable it may be enhanced by chronic systemic diseases such as diabetes The first type also described as *agricultural anthrax* which takes the form of malignant pustule is due to contamination of the skin with material from infected animals rarely the bites of insects (Louisiana seven cases) It is quite seasonal the incidence depending on the extent of anthrax in the animals The ingestion of infected food such as sausage or the improperly cooked meat of anthrax animals may give rise to the intestinal form of the disease (Gipsies South African natives) milk is seldom involved since the cow sick with anthrax is removed Infection by ingestion is quite rare in the United States Cases of anthrax from *shaving brushes* (0 08

patients showed no objective symptoms they were restless and revealed in their facial expressions great anxiety and concern for their health Collapse cyanosis and apo plectic death terminated the infection of the majority within one to three days, in one case the course was prolonged for eleven days At autopsy localized phlegmonous hemorrhagic infiltrations and carbuncles were noted in the ileum and cecum and hemorrhages in the myocardium and brain

Diagnosis —The diagnosis of anthrax is greatly facilitated when the cutaneous lesions are characteristic and when the an amnesis and occupation of the patient sug gest the nature of the infection In case no information is available the differential di agnosis between an anthrax carbuncle and a simple coccal infection requires laboratory assistance Any physician possessing a micro scope of medium power and some staining reagents can make an early diagnosis and thus reduce the risks attending the disease If a vesicle has formed films are made from the serum and stained If it is already broken gentle scraping of the pimple or puncture of the eschar will produce serum rich *in typical encapsulated bacilli when* stained with a polychrome eosin methylene blue stain (Wright or Giemsa) Their di rect cultivation on peptone agar should al ways be attempted In case the specimen has to be shipped the tissue serum should be dried on silk threads or a sterile glass slide On occasion both the smear and cul ture may show anthrax bacilli in small num bers or even none at all while several varieties of cocci may grow in the culture Re peated examinations and cultures are therefore indicated In view of the occurrence of anthrax like bacilli on the skin it is impera tive that all anthrax diagnoses should be confirmed by animal inoculations preferably on guinea pigs or mice In pulmonary an thrax the bacillus has been found micro scopically in the sputum and in the pleural exudate The vomitus should be inspected when gastro intestinal anthrax is suspected

During the terminal stages of the disease and sometimes when severe general symp toms are present the bacillus may be cul tivated from the blood stream if not less than 20 cc of blood are taken Even in non fatal cases and in the absence of symptoms indicative of generalization the anthrax ba cillus may be isolated from the blood stream Blood or spinal fluid, after it has been treated with 3 per cent acetic acid solution may be centrifugalized and the sediment ex amined with a Wright s stain for bacilli Estimation of the phagocytic power of the leukocytes in the hands of an expert may be of diagnostic and prognostic importance

Prognosis —It is quite generally recog nized that the prognosis in external cuta neous anthrax is favorable provided the pustule is not on the neck or face and has not been irritated by physical and chemical procedures Moreover, if the nature of the pustule is correctly and promptly diagnosed the patient placed in bed and specific treat ment is instituted not later than the third day the chances for recovery in the great majority of infections are favorable To be sure the statistics amply attest to the event ful recovery without complications or se quelae without specific treatment On ac count of the variable individual disposition of man to anthrax it is doubtless true that cutaneous even visceral infections are not as deadly as popular belief would indicate *Thompson reports on the anthrax infections* of veterinarians only one of the twenty cases (eighteen with malignant pustule one throat infection and one generalized) ended fatally However it is well to remem ber that the general fatality rate is around 20 per cent (Holland and U S A) but may be as high as 40 per cent There is generally a low fatality rate for tannery anthrax but a high rate for the form that results from animal contact Septicemia with and with out involvement of the viscera and some times meningitis are serious complications In fact double and multiple infections occur at times and recurrences are possible though not usual When the eruption assumes the form of anthrax edema indications of di minished resistance are obvious and the out come may be in doubt In respiratory and *alimentary anthrax the prognosis is grave* largely on account of the extensive visceral destruction and the presence of a bacteremia (up to 300–400 bacilli per 1 cc) The pres ence of bacilli in the blood culture justifies an unfavorable prognosis although by mod ern therapeutic procedures such as specific serum dramatic cures may be achieved

leukopenia with 60 to 85 per cent polymorphonuclear leukocytes Despite the alarming aspect of the carbuncle the general manifestations of illness may be exceedingly slight On the other hand even the early stages of the local process may be accompanied by profound malaise, vomiting, circulatory collapse, cyanosis, profuse perspiration diarrhea and subnormal temperatures Death may take place in from three to five days Blood cultures usually reveal anthrax bacilli

The presence of bacilli in the blood stream does not always constitute an unfavorable prognosis In fact the mode of action of the anthrax bacilli is by no means clearly understood The invasion in the blood stream occurs late remains confined to the blood vessels of the liver lung spleen and kidney and is accompanied by severe toxic manifestations

It is not unlikely that embolic bacillary occlusions of the capillaries and the formation of poisons in the extravasations of blood into the organs are principally responsible for the severe symptoms and deaths According to Szendey, cerebral hemorrhage is present in at least 40 per cent of the fatal cases Cyanosis and respiratory distress are always grave symptoms

2 Malignant anthrax edema is observed in the loose connective tissue of the eyelid hand neck thigh and mucous membranes It is characterized by a doughy soft transparent faintly reddish or anemic infiltration and swelling without papules and vesicles following rather than preceding constitutional symptoms Rarely circumscribed it spreads rapidly and is apt to terminate in extensive sloughing and gangrene In general the outcome of the edematous form is less favorable than that of the carbuncle

(*B*) *Internal Anthrax*—3 Pulmonary anthrax presents no characteristic clinical symptoms The onset is sudden with rigor and fever which may be slight or excessive Aside from general *malaise* headache and circulatory disturbance the patients may complain of a feeling of tightness in the chest and difficulty in breathing which in some may be accelerated to the extent of 40 to 50 respirations to the minute The sensorium is mostly clear The auscultating signs are usually those of a bronchitis An examination of *the nose larynx and pharynx* discloses reddening and swelling of the mucosa With increasing dyspnea, cough and pain in the chest pneumonic infiltration or even pleuritic exudates, becomes discernible, In the frothy, occasionally blood tinged sputum, anthrax bacilli may be demonstrated Death may occur within eighteen to forty eight hours, when the disease is of longer duration (up to ten days) delirium and unconsciousness govern the clinical picture On the other hand, absence of the severe symptoms usually accompanying acute infections and the rapidity with which collapse sets in are characteristic features of this form of anthrax *Not infrequently*, *the disease* is suspected on account of the occupation which subjects the patient to inhalation of dust from hairs soiled with spores Massive doses of serum should then be administered without awaiting the bacteriologic diagnosis since without treatment the mortality is nearly 99 per cent McKitterick and Pearson report as a complication the damaged vision in a two and one half year-old child with pulmonary anthrax

4 Gastro intestinal Anthrax—This form which is rare in the United States may result from the ingestion of infected food or may follow the external type when the organisms are carried to the mouth from the external lesions it may occur as a secondary manifestation of anthrax in some other part of the body Sinai calls attention to instances of symptomless infections in a group of people who ate partly cooked meat from a calf which had succumbed to anthrax The sera of fifteen of thirty eight persons who had ingested the meat gave positive precipitin reactions with a specific anthrax serum In an epidemic due to sausages involving thirty people Solowieff (1930) noted the following symptoms in the cases which he subsequently autopsied persistent vomiting constipation rarely diarrhea the intestinal tube was usually empty and occasionally blood tinged fecal material or pure blood was discharged The abdomen was distended and tender and since a peritonitis was always present accumulations of exudate were usually discernible The temperature usually remained normal rarely exceeded 102 2° F and following profuse perspiration dropped to normal Although the

arsenicals to antianthrax serum on account of the risk of serum sickness in veterinarians (Thompson 1937) Gilbert treated nine cases with novarsenobenzene and only two infections ended fatally while among untreated patients the mortality is said to be nearly 100 per cent in African natives The serum treatment remains however, the method of choice and is doubtless the only therapeutic procedure which may be employed with any degree of hope in the generalized visceral forms of anthrax Of seven cases with generalized infection Sabolotnyi treated four with serums with three recoveries while three were not treated and all died Sulfapyridine sulfathiazole sulfadiazine and sulfanilamide in the order named have been used by Gold in the treatment of forty two cases of anthrax with excellent results in thirty nine The drug of choice is sulfathiazole in large doses If the edema is not controlled by the third day large doses of antianthrax serum must be given In the treatment of anthrax preference is now given chemotherapy with sulfonamide compounds

Prevention —The prevention of the disease in man must first be directed to a suppression of the infection in animals by veterinary control measures disinfection of all raw materials in which horsehairs hides wool and other substances are liable to harbor the anthrax spore The sick animals must be isolated or killed and carcasses must be promptly disposed of by burial with lime (at least three feet deep) or by burning without skinning Vaccination of the live stock with carbozoo —a spore vaccine containing 2 per cent saponin (Mazzuchi and Hruska)—is being employed with considerable success The disinfection of the hair and wool from anthrax infected or suspected areas may be done by boiling for three hours or with steam under pressure Hides and skins are treated in a hydrochloric acid and salt mixture at 40° C for six hours Workers in tanneries and wool factories may be protected by rubber gloves and aprons and by proper ventilation to carry off the dust. Active immunization of workers exposed to goat hair imported from China with a heat killed anthrax vaccine has been tried by Gold but two cases so vaccinated were not protected

Some writers claim a recovery rate of 10 per cent or more, but in many of these cases a bacteriologic diagnosis was not made The true nature of mild cases may occasionally be suspected but is rarely proved An attack of the disease, if it produces immunity induces a resistance of only short duration Second attacks of cutaneous anthrax have been known to occur within a year

The average hospital stay is about two weeks and provided the ulcer heals in two weeks, the patient returns to work within five to six weeks

Treatment—In recent years the treatment *of anthrax in man has* been placed on a sound foundation and many of the traditional procedures and conceptions have been abandoned Few authors still recommend incision excision or cauterization of the carbuncle or other meddlesome local manipulations except in diabetic patients (Rodriguez Villegas) Almost all reports stress the need for absolute rest of the patient in bed and immobilization of the affected part As local antiseptic dressings mercury bichloride (1 2000) potassium permanganate (1 1000), borated petrolatum or ichthyol are recommended

The use of the *specific antianthrax serum* first introduced by Scalvo (1895–1896) and administered intravenously or intramuscularly is now universally recommended as a dependable treatment of external or internal anthrax The early administration of a large dose of serum is an essential part of the treatment In the writer s experience 300 to 600 cc serum diluted with 10 to 15 per cent glucose solution and infused intravenously lead in most cases to a disappearance of the edema, general malaise and headache, and a return to normal temperature and pulse The serum may be given in one, two or three large doses The first dose *of serum should not be less than 150 to* 300 cc Repeated small doses rarely are as effective as two or three large doses except *in the infections with* bacteremia when daily two to four injections of from 40 to 50 cc of serum are given Nilson saved a case of anthrax bacteremia by treating it with 13 400 cc of serum of which 7600 cc were given intravenously There is no necessity to give serum until the lymphadenopathy has receded Local administration of serum around the carbuncle is contraindicated in fact in some cases decidedly harmful In the series of cutaneous anthrax cases treated by Legge Hodgson Gold and others the mortality was reduced in 7 per cent According to Smyth the case fatality rate of 312 cases treated with serum was 30 or 9 per cent The way in which the serum acts is unknown it is supposed to contain opsonins

More and more combination treatments with arsenicals and serums are coming into favor The method of choice is apparently 2 to 3 injections of 0 6 to 0 9 Gm *of neo*arsphenamine on the first and second day after the injection of the specific serum Eurich (1933) has had a mortal*ity of* only 5 per cent in his last 200 cases of cutaneous anthrax so treated If serum is not available, neoarsphenamine in *dosage of* 0 75 Gm three times a day every three to five days may be tried In 27 cases so treated no deaths were *reported* Danish workers prefer

Fig 94—Cutaneous anthrax in a butcher before serum treatment.

Lepus) No human infections have been traced to domestic rabbits, although spontaneous disease has been observed in these species The infective agent enters through wounds or through the unbroken skin (2) *Bites of insects* of determined species (ticks and *Stomoxys*) and of undetermined species (mosquitoes and fleas?) are responsible for many cases The deer fly (*Chrysops discalis*) is the principal source in Utah (Hillman and Morgan), the wood tick (*Dermacentor andersoni*) and dog tick (*Dermacentor variabilis*) cause infections in the western and southern states (3) *Bites* of such animals as cats opossums coyotes dogs skunks squirrels hogs muskrats raccoons lambs etc have been followed by tularemia (4) *Contact with sheep* (in particular with the ticks and their fecal droplets in the wool of sheep) is responsible for occupational infections in sheep shearers (5) *Skinning and dressing of mammals* [tree squirrels coyotes skunks deer muskrats foxes and water rats in Russia (*Arvicola amphibius*) birds (quails sage hens chickens) and cold blooded animals (bull snakes fish baited with rabbit meat)] (6) *Laboratory infections* are observed so frequently (at least 60 are known) that some writers have expressed the opinion that every one who works with infected animals will ultimately contract the disease The mode of transmission is obscure Russian workers suspect the aerogenic pathway because the wearing of a face mask apparently prevents this infection

B tularense requires no particular portal of entry for its penetration It is not surprising consequently that in addition to contact infections tularemia has been caused by the *ingestion* of partially cooked rabbit meat (twenty cases with twelve deaths Amoss and Sprunt) and by the drinking of water from a brook contaminated by water rats (43 cases in Russia Karpoff and Antonoff 1935) The contagiosity of the infection is very low No proven human case to case transmission has been reported an increasing incidence of pulmonic tularemia however suggests the possibility of a transmission by way of the sputum Multiple familial infections by handling the same rabbit have been reported by Kavanaugh

Ecology of the Reservoirs—The key factors in the transmission of tularemia are ticks and wild rodents (representatives of the Leporidae, Sciuridae and Muridae) For its propagation in nature *B tularense* depends entirely on the wood ticks *Dermacentor andersoni* Stiles, and the dog ticks *Dermacentor variabilis* and *occidentalis* which feed on rabbits and other rodents A hereditary transmission through the eggs of the tick to the larvae and nymphae maintains the well regulated organization of the chain of infection This problem of the multiple factors involving the bionomics and ecology of insects and rodents varies from region to region and from country to country and thus creates a complex kaleidoscopic epidemiologic picture which thus far has been sketched only in its broader outlines

Morbid Anatomy.—The autopsy reports (56) placed on record by Foshay, Lillie and Francis stress in both the acute and subacute stages of the disease focal areas of necrosis throughout the body in various phases of evolution Macroscopically whitish yellow foci ranging in size from those hardly visible to the eye to those measuring 8 cm in diameter are found in the lymph nodes spleen liver kidneys and in a certain percentage of the cases in the lung Necrobiotic processes consisting of nuclear fragmentation and infiltrations with polyblasts in the early stages are replaced later by a central area of detritus cuffed by monocytes and fibroblasts in a fairly characteristic radial arrangement and peripherally encircled by lymphocytes and an occasional cell of the Langerhans type Pulmonary tularemia is characterized by grayish white necrotic foci surrounded by hyperemia and extravasation which extend from the pleura into the parenchyma of the lung

Symptoms—The period of incubation in tularemia is from one to ten days according to Francis it does not exceed five days the average being three and one tenth days while Kavanaugh places it at four and one half days Only the typhoid type proceeds as a general disease without local processes Since the *onset* is sudden the patient usually remembers not only the day but the hour at which he fell ill Severe headache vomiting chills and fever with an initial rise in temperature above 104° F accom

TULAREMIA

(Plague like Disease of Rodents Deer Fly Fever Tick Fever, Rabbit Fever)

Definition —Tularemia is a specific infectious disease caused by *Bacterium tularense* It is a potent factor in the destruction of wild animal populations acting as a heterogeneous infection chain with a broad spectrum of infection in which a great variety of rodents and insects participate as reservoirs and vectors Man may enter into the chain accidentally or occupationally by contaminating his hands conjunctival sac or buccal cavity with the infected internal organs and body fluid of mammals birds and insects, or by the bite of an infected blood sucking fly or tick Wild rabbits and hares have been the principal sources for the disease in man

History —Tularemia is not a new disease without a doubt having existed unrecognized for a long time It is proudly called a truly American disease because of its discovery in America (California) and because Americans contributed the basic knowledge concerning it McCoy in the course of his studies on plague in 1910 discovered a disease among ground squirrels (*Citellus beecheyi*) characterized by pathologic lesions similar to those of plague This plague like disease of rodents was encountered in rodents shot or found dead in Tulare County California When McCoy in cooperation with Chapin succeeded in isolating the causative organism he named it *B tularense* Shortly thereafter Wherry established bacteriologically the first infection in a human being and recognized the hare as an important reservoir of the disease Francis in 1919 and 1920 investigated rabbit fever in Utah and discovered that the blood of a rancher who had been bitten on the neck by a deer fly and had died on the twenty sixth day of his illness produced in the guinea pig the plague like disease described by McCoy In rapid succession he reported the discovery of *B tularense* in jack rabbits the experimental transmission of the disease by the bite of the deer fly (*Chrysops discalis*) and the rabbit louse (*Haemodipsus ventricosus*) the cultivation of the organism on new media and the serological diagnosis The role of ticks as important reservoirs and vectors of tularemia has been elucidated by Parker and Spencer (1926 and 1929) and by Green (1929)

Bacteriology —*B tularense* is a sho[rt] gram negative rod pleomorphic forms a[re] coccoid, occasionally bipolar but nonsporin[g] It is capsulated and according to Ohara slightly motile In smears it is gram neg[a]tive but stains well with fuchsin or cryst[al] violet, while in sections it is not demo[n]strable with certainty *B tularense* is an i[n]tracytoplasmic parasite with great affin[ity] to ectodermal epithelial cells (Buddingh a[nd] Womack 1941) Under aerobic conditio[ns] it grows well only on gelatinized hen s egg yolk and rabbit blood glucose cystine or thioglycolate agar Heating at 58° C for 10 minutes or cooking kills the organisms The usual disinfectants, for example 1 0 per cent tricresol, destroy the bacteria in two minutes It remains viable in pure neutral glycerin at —14° C for two years Preservation at —76° C is likewise effective for months The guinea pig is used for laboratory tests and the mouse for testing specimens of sputum

Epidemiology and Ecology of the Reservoirs —Tularemia as an endemic disease of man (over 10 118 cases known) has been observed in forty six states and the District of Columbia of the United States and Alaska it has been reported from Canada Japan the Soviet Union and in recent years in epidemic proportions from Europe (Sweden Norway Bohemia Austria Turkey Germany) Cases of natural infection occur in every month of the year but they are most prevalent in summer time in the western states where ticks (March to August) and deer flies (June to September) are the cause of infection or when jack rabbits are being dissected (April to October) in the eastern states when East of the Mississippi River Game Laws permit the hunting of cotton tail rabbits (November to January) The highest annual incidence on record is that of 261 cases in 1939 Men and women of all races and all ages are equally susceptible to the disease

According to Francis at least twenty methods by which man may be infected with tularemia are known The most important sources of infection are (1) Over 90 per cent of the human cases in the United States are traceable to contact with infected *rabbits* (cotton tail rabbit *Sylvilagus floridanus* jack rabbit and snowshoe hare

or may develop on a hematogenous basis secondary to some primary focus on the skin or elsewhere In the first group pulmonary symptoms less abrupt than in the pneumococcic types initiate the disease hacking non productive cough dyspnea fever malaise and occasional chills are present Pleuritic pains may be a dominating symptom Cases of milder involvement appear as atypical pneumonias in which the pulmonary lesions may last for a month One laboratory infection probably caused by the aspiration of bacteria from an incompletely killed suspension of *B tularense* was tentatively diagnosed as psittacosis until the specific bacterium was isolated from mice inoculated with the sputum Primary pneumonic tularemia is not well known but according to recent reports the incidence throughout the country is strikingly on the increase In another large group of cases pulmonary tularemia develops in patients having well recognized tularemia with ulcers or infections of the eye Cases of this type offer no problem in diagnosis as a rule the sickest patients are most likely to have involvement of the lungs Pleuritis usually is present and the development of a pale yellow slightly cloudy pleural effusion of high specific gravity but low cellular count (2000 to 5000 per cubic millimeter) is of great diagnostic value The pneumonic consolidation as parenchymal confluent or lobular bronchopneumonic infiltration consists of small patchy later large coalescing areas The physical signs may vary from day to day indicative of a migratory type of pneumonia usually more extensive in one lung than in the other When the process is predominantly necrotizing in character gangrene cavitation and pulmonic abscesses develop in those cases in which the disease is most severe Despite large cavities or abscesses the sputum is moderate in amount, mucopurulent and rarely blood tinged or rusty X ray films taken from a few days to two weeks after onset may reveal a slowly advancing lobular type of consolidation The mediastinal and peribronchial lymph nodes almost always are enlarged

Oral and Abdominal Tularemia—Ingestion of insufficiently cooked wild rabbit meat or water contaminated with *B tularense* may cause a violent local process in the form of a necrotizing pharyngitis or angina abscesses on the roof of the mouth ulcers in the pharynx and nasopharynx fever enlargement of the submaxillary and anterior cervical lymph nodes and, in some cases conjunctivitis Vomiting excruciating pains in the abdominal regions and diarrhea begin either during the febrile period or after the temperature has fallen The course may be fulminant children have developed convulsions become stuporous and died in the first week of illness In adults there may be enlargement of the regional lymph nodes accompanied by fever but no deaths have been reported Russian observers have reported the persistence of enlarged submaxillary lymph nodes up to eight months after infection

Complications—Symptoms of general peritonitis with the finding of plastic exudate at autopsy (Francis Fulmer) and persistent ascites requiring tapping three and five months after onset have been reported Appendicitis diarrhea and intestinal hemorrhages may be present during the last days of illness Occasionally pericarditis pneumothorax thrombosis of the veins or osteomyelitis complicate the convalescence Meningeal or leptomeningeal localization demonstrated by the isolation of *B tularense* from the spinal fluid usually is fatal Diffuse encephalitis in acute tularemia has been observed at autopsy by Hartman

Convalescence and Prognosis—Many of the patients are ambulatory In about one-third of the cases recovery even without complications is slow but *confers a permanent* immunity According to Foshay the mean duration of fever is twenty six days the duration of the adenopathy from three to four months and the duration of the disease five and one half months Even though clinical recovery is evident the *B tularense* because of its facultative intracellular parasitism may remain alive in the tissue for months and perhaps years (Blackford Foshay and Mayer) Pulmonary tularemia has a high rate of fatality (62 5 per cent) while the average mortality for tularemia in the United States has been reported by the United States Public Health Service as 5 6 per cent (Foshay 6 0 Simpson 11 0 per cent) Death may occur within four days to nine months after onset

panied by general aching and weakness are followed by prostration, sweats and loss of weight Delirium and stupor may be present in the more severe cases The temperature records are not particularly characteristic, they may present a relapsing undulating, remittent or continuous type The constancy of the sequence of initial rise remission and secondary rise, however is striking in the cryptogenic type of the disease Continuous high temperature is noted in cases with extreme toxemia In cases of average duration the febrile period may last from ten to fifteen days and in the more severe forms the disease usually runs a course of from three to four weeks Febrile periods or elevation of temperature of one degree may persist for three weeks Eruptions of the skin in the form of a papular exanthema on the palmar surfaces or of roseola pustules and petechiae on any part of the body may appear at any stage in all forms of tularemia These rashes may be the result of toxic acion or bacterial emboli They heal by absorption or exfoliation

Enlargement of the spleen is evident in about one quarter of the cases and is not great, on rare occasions it extends from three to four finger breadths below the costal margin Tenderness and pain indicate the existence of a perisplenitis A slight to moderate polymorphonuclear leukocytosis (12 to 15 000 cells) may be noted during the course of the disease Secondary anemia is common The urine is diminished in amount and febrile in character Myalgia, arthralgia and neuralgia occur frequently

Cutaneous Tularemia—Within from thirty six to forty eight hours after the onset of the disease with slight painful enlargement of a lymph node the patient usually notices that a previous cut or sore is inflamed and tender This primary lesion evolves from a papular stage to a pustular stage with a necrotic plug The pustule is supplanted by a punched out ulcer with scanty serous discharge which ultimately is replaced by a scar Not infrequently painful lymphatics with or without subcutaneous nodules (nodular lymphangitis) resembling mycotic lesions extend from the ulcer to the regional epitrocheal or axillary lymph nodes The nodes vary in size from that of an almond to that of a small orange Sometimes several groups of nodes show reactions to a single primary lesion, for example, the axillary and supraclavicular nodes may react to a single ulcer on the shoulder Some lymph nodes suppurate in from one to twenty four months, others remain hard tender and palpable for periods up to twelve months and ultimately may require incision

Ophthalmic Tularemia—The primary localization is in the conjunctival sac it occurs unilaterally and rarely bilaterally Itching lacrimation photophobia and pain are early subjective symptoms which are accompanied by swelling of the pre auricular, parotid submaxillary and cervical lymph nodes The eyelids are swollen and the chemotic deep red conjunctivitis is studded with small discrete yellow nodules Occasionally both the palpebral and bulbar conjunctivae may be covered by a gray translucent organized exudate Punched-out ulcers follow the breakdown of the necrotic nodules A mucowatery or purulent discharge accompanies the conjunctivitis for from three to five weeks, after which the swelling recedes and complete recovery is the rule Suppuration of the regional lymph nodes is fairly common in ophthalmic tularemia Dacryocystitis, corneal ulcers permanent impairment of vision optic atrophy and blindness have been observed following perforation of the cornea

Cryptogenic Tularemia—The symptoms of a general systemic infection are characterized by fever profound toxemia with drowsiness or a typhoidal state abdominal distress and prostration It is of interest that with few exceptions (in Russia) the laboratory infections in persons who wore gloves when working on guinea pigs rabbits and mice revealed no primary skin lesion or tularemic lymphadenitis The cryptogenic type of tularemia however may be caused also by the bites of insects or by contact with rodents Severe pulmonary symptoms in at least 50 per cent of the cases or intestinal symptoms may follow

Pleuropulmonary Tularemia—The symptoms of pulmonary tularemia are variable and the diagnosis without laboratory aids is difficult The disease may begin as an inhalation infection with pulmonary symptoms

plished by supervision of interstate shipments of wild hares and of their sale for food in markets and restaurants

LEPROSY

Definition—Leprosy is a chronic infectious and contagious disease caused by the *Mycobacterium leprae* It presents a great variety of signs and symptoms owing to its tendency to implicate different tissues of the body, and frequently results in death either directly or indirectly as the result of grave complications

History.—There is evidence that leprosy occurred as long as two thousand years before the beginning of the Christian era Several references to the disease are made in the Old Testament It was common in Europe between the second and seventh centuries In the eleventh and twelfth centuries a great epidemic began which devastated the populations of England and the continent lasted for several centuries and gradually subsided during the sixteenth century In parts of the Orient (Egypt India China) it probably existed several thousand years ago In Europe the segregation of the victims of the disease in leprosaria led to a gradual local wiping out of the scourge so that at present the disease occurs only endemically and sporadically in different regions chiefly in Iceland Scandinavia Russia, northeastern Germany Galicia Hungary the Balkan Peninsula Spain Portugal southern France Greece Italy Turkey Africa and parts of South America

Incidence—Very few parts of the world are today entirely free from the disease Leprosy is common in China Japan the Philippines the East Indies Malaysia Australia India Turkestan Arabia and many other parts of Asia It is frequently encountered in Egypt northern and southern Africa, and many other coastal countries of that continent In the Western Hemisphere it is most common in the Hawaiian Islands Mexico and Central America the West Indies the northern countries of South America and in Paraguay In the United States foci have existed for many years in Louisiana Minnesota and South Carolina Sporadic cases are not infrequently seen in the larger cities of the Atlantic and Pacific seaboard because of immigration from countries mentioned above A few foci exist also in Canada

Etiology—Leprosy is caused by the *Mycobacterium leprae* which was discovered in 1873 by Hansen The mode of invasion of this organism is not definitely known but a considerable amount of evidence points to a probable transmission by inhalation In many lepers the nasal septum seems to be the first site of attack The mucosa of the gastro intestinal tract might be the path of contagion Some investigators believe that certain insects such as the bedbug mosquito fly itch mite etc play the role of intermediary host but this has not been confirmed That the disease is contagious there is no doubt but it is not readily contagious and can be transmitted from one person to another only after long continued and intimate contact Predisposing factors —bad hygiene filthy environment and unsanitary habits of living—are usually found to play a role in the transmission of the malady

Leprosy is most common in individuals between twenty and fifty years of age but it often attacks children It is rarely seen in infants The disease is much more often encountered in the male than in the female It is not hereditary and an inherited predisposition to it has never been demonstrated Much research work will be necessary to arrive at definite conclusions with respect

Diagnosis—Tularemia should be considered in every doubtful case of fever or atypical pneumonia in which the patient may have been exposed by contact with some animal The following immunologic and bacteriologic tests in the order mentioned are valuable diagnostic aids

(1) *Intracutaneous or percutaneous allergic skin tests* with detoxified formalin-killed *B tularense* as antigen (Foshay) may yield positive reactions on the third day of illness Since hypersensitiveness of the skin is a notable feature of tularemia in the early as well as the late stage of the disease this method deserves more frequent use than has been customary in the past The inflammatory response is similar to the reaction to tuberculin and attains maximal size forty eight hours after injection or application on the scarified skin

(2) *Agglutination and Complement Fixation Tests*—Specific antibodies in the blood never appear before the tenth or twelfth day of the disease and thus the agglutination test is of little help during the first period of the disease when it is most difficult to diagnose clinically The sera of patients with brucellosis furthermore may give positive reactions with tularemic antigens When repeatedly applied in order to determine a rise in the titer of the agglutinins the test is valuable and irreplaceable for retrospective diagnosis

(3) *Cultures* on dextrose cystine or thioglycolate blood agar, inoculation of guinea pigs with blood, pleural effusions and infected material or of mice with sputum during life and with blood from the heart at autopsy should be made when agglutinins are absent and the course of the disease suggests tularemia The danger to the laboratory worker who makes use of direct cultivation or animal tests should be recognized

Differential Diagnosis—Tularemia may masquerade in a variety of forms the signs and symptoms are so similar to many other acute infectious diseases notably influenza psittacosis atypical pneumonia undulant fever typhoid and septicemia that differential diagnosis is difficult The subcutaneous nodules and the enlarged lymph nodes have been diagnosed erroneously as sporotrichosis and at autopsy tularemia has been mistaken for tuberculosis In any locality where the infection is prevalent among rodents, the clinician must have tularemia in mind

Treatment—The treatment of tularemia is largely symptomatic During the febrile stage the patient should be at rest in bed Generous feeding is indicated Intravenous injections of physiologic solutions of sodium chloride seem to allay the severe toxemia According to a few reports sulfathiazole given in amounts of 2 Gm every three hours for the first two or three doses in order to insure an early high blood level and then 1 Gm every three hours has given encouraging results Sulfadiazine may also be tried Convalescent serum has not proved to be of value The specific antiserum prepared by Foshay was found ineffective when tested experimentally on animals (Francis and Felton) but in the hands of the discoverer when used early and in amounts of from 10 to 20 cc intravenously it apparently had a desensitizing effect and reduced the duration of the adenopathy and of the disease The use of vaccines during the acute stage has been tried and abandoned Local cutaneous lesions should not be incised, they are best treated by hot moist applications containing some germicide which makes the handling of dressings less dangerous Treatment by x ray has been tried with suggestively good results The most satisfactory treatment of the conjunctival inflammation is with hot applications and frequent lavage with warm physiologic salt solution Suppurating lymph nodes should be incised only after they show definite fluctuation Since febrile reactions and even chills may follow such a procedure surgical treatment of tularemia should be judicious

Prevention—Tularemia as an everlasting endemic and frequently epidemic disease of rodents and with a latent parasitism in insects cannot be eradicated Since no prophylactic vaccine has been worked out it is imperative that sportsmen butchers and those who live in regions where the infection prevails should be educated to the dangers of this disease Rubber gloves should be worn while dressing wild rabbits Laboratory workers should use face masks To render the meat of rabbits harmless thorough cooking is imperative Some reduction in the incidence of tularemia would be accom

they finally become elevated and nodular Usually they appear in crops In the larger lesions the circular central portion sometimes becomes white and depigmented As the malady progresses nodular infiltrations and thickenings of the skin appear on the forehead in the region of the eyebrows in the lobes of the ears and on the cheeks nose and mouth producing the so called leonine expression The outer portions of the eyebrows are lost The hair of the scalp remains unaffected These erythematous and nodular lesions may eventually attack any portion of the skin so that large surfaces become involved The fresh lesions are usually pink, red or violaceous in color the older lesions turn dark brown At times there is a distinct widening of the mouths of the hair follicles on the surface of the nodules The entire skin may present a peculiar dusky unhealthy hue the forearms and legs assume a dry scaly appearance like ichthyosis especially pronounced in patients with dark skins The nails frequently present small nodular infiltrations at their bases and are at times striated and distorted There is usually a well marked adenitis In some cases the legs swell as in elephantiasis While some of the nodules remain unaltered for long periods others soon ulcerate often as the result of injuries Spontaneous healing of ulcers and absorption of unbroken nodules may take place In advanced cases severe ulcerations go on to necrosis of the deeper tissues which results in loss of the fingers and toes (*lepra mutilans*) Many of the lesions leave depigmented or hyperpigmented scars

Small nodular lesions frequently develop on the mucous membrane of the pharynx nose larynx conjunctivae and less often on the tongue In some of these a softening and breaking down produces ulcerations contractures and scars The voice becomes hoarse The conjunctival lesions lead to keratitis scleritis and iritis and often to blindness Perforation of the nasal septum is not uncommon

The course of nodular leprosy is usually protracted it may last from ten to twenty years or even longer Most patients die of complications resulting from intercurrent affections such as tuberculosis pneumonia bronchitis nephritis etc in others death is caused by malnutrition, exhaustion and toxemia In rare instances the superficial evidences of the disease regress spontaneously and an apparent recovery takes place

Maculo-Anesthetic Leprosy (Lepra Nervorum) —Maculo anesthetic leprosy is characterized by macular lesions and large flat patches and by disease of the nerves Prodromal symptoms are often absent or pass unnoticed by the patient and are usually less evident than in the nodular type Usually beginning on the extensor surfaces of the extremities and on the back round, oval and gyrate macules and plaques appear distributed more or less symmetrically on both sides of the body Their edges are sometimes well defined at other times they merge imperceptibly with the normal skin The color of the lesions varies from red to violaceous or brown Rings and irregular polycyclic figures are formed the edges reddish brown the interiors yellowish or dull white in tint The surface is smooth and free of scales Sometimes acute erythematous patches appear which are ephemeral and simulate *erythema multiforme* In exceptional instances the earliest cutaneous lesion consists of a group of bullae which later become severe ulcers

The affected areas of skin are at first hyperesthetic and pruritic but as the malady progresses they become anesthetic because of implication of the nerve trunks The superficial nerve trunks such as the ulnar tibial peroneal and postcervical become thickened and present fusiform swellings which may often be readily palpated This invasion of the nerve trunks and their branches results in loss of sensibility to touch heat and cold As time goes on complete anesthesia supervenes Traumatisms and burns occur without the patient s knowledge, these ulcerate and suppurate and often result in frightful deformities Trophic changes occur in various groups of muscles the interossei thenar and hypothenar eminences frequently being first affected Contractures of the tendons then ensue and produce the characteristic clawhand or leper claw Atrophy of the facial muscles gives the features a masklike appearance Perforating ulcers of the soles of the feet are common In advanced cases there may be extensive mutilations

to modes of transmission, sites of inoculation, the role of insects as intermediary hosts of the bacterium the susceptibility of exposed persons, and many other phases of the etiology of the disease

Morbid Anatomy —Leprosy is a neoplastic disease included in the group known as infectious granulomas The new growth produced by the causative organism the *Mycobacterium leprae*, is a granuloma composed of connective tissue cells epithelioid cells vacuolated giant cells together with mast cells lymphocytes and plasma cells Scattered through this infiltrate are variable numbers of large ovoid cells the so called *lepra cells* the exact nature of which has not been definitely determined

The bacterium of leprosy closely resembles that of tuberculosis both in respect to its morphology and its reactions to stains It is from 5 to 6 microns in length and frequently presents a beaded appearance sections of tissue often reveal enormous masses and clumps of bacteria, the organisms also occur in the lepra cells in the walls of blood vessels and in the sheaths of nerves In the cutaneous nodules of leprosy in discharges from ulcers and from the mucosa of the nose and pharynx large numbers of organisms are frequently found When the disease is advanced bacteria may be found in all the viscera particularly in the liver and spleen Cultures of the organism on artificial media have been grown successfully by Duval Clegg, Currie Wellman Hollmann and others Duval among others recently succeeded in inoculating animals with the disease Honeij found the organism in the blood of nine out of twenty eight lepers More recent investigations seem to throw considerable doubt on the results of the work thus far carried out on cultural and animal inoculation experiments (See Lepra Handbuch der Haut- u Geschlechtskrankheiten Vol X/2 Edited by J Jadassohn Julius Springer Berlin 1932)

The histopathologic picture of sections from leprous tissue often closely simulates that of syphilis and of tuberculosis when bacteriologic identification of the causative organism fails differentiation of these diseases by means of microscopic examination of tissue is often a difficult task

Symptoms —Leprosy is characterized by a great variety of symptoms partly because of the fact that different tissues of the body are concurrently affected and partly because of the appearance of secondary lesions as complications

The *period of incubation* is extremely variable it may be several months or perhaps twenty or thirty years In one of the writer's patients it was estimated to be twenty three years

The *preeruptive manifestations* are those common to other infectious diseases and consist of backache, pains in the muscles and joints digestive disturbances, neuralgias and headaches *Rhinitis* is a common prodromal symptom Sometimes there are attacks of fever simulating malaria Occasionally prodromal symptoms are lacking or the nervous system is chiefly implicated and there may be attacks of pruritus hyperesthesia, anesthesia and various disturbances of sensation particularly with respect to response to heat and cold

According to the main point of attack of the invading organisms—the skin or the nervous system—the disease assumes two clinical forms—nodular leprosy and maculo-anesthetic leprosy A third form mixed leprosy presents the symptoms of both varieties one merging with the other Clinical symptoms are classified as (1) lepromatous (2) neural and (3) mixed The new classification recently adopted uses the symbols C (cutaneous) and N (neural) Later the symbol L (lepromatous) was substituted for C (cutaneous) Mild moderate and advanced cases are labelled respectively 1 2 3 Thus a mixed case with severe cutaneous lesions and mild neural changes would be designated as L3 N1 In the United States most of the patients have the mixed form of disease

Nodular Leprosy (Lepra Tuberosa) —Nodular leprosy is characterized by the formation of nodules or lumps in the skin The lesions are usually preceded by reddish and brownish red spots which vary in size from ¼ inch to several inches they may be flat or slightly elevated the surface is smooth and frequently has a peculiar velvety texture These develop most commonly on the back of the hands and feet and on the face Some spots gradually fade without leaving a trace other slowly increase in size until

giene etc The prognosis of the nodular and mixed varieties is far less favorable

Treatment—Like tuberculous patients lepers are apt to contaminate their immediate surroundings with secretions and excretions Coughing sneezing and spitting presumably play an important part in the dissemination of the disease, the urine and feces also harbor bacteria Patients with open lesions—excoriations ulcers secreting wounds etc both of the skin and mucosae—should be strictly segregated The United States Government maintains a leprosarium in Louisiana Large cities provide housing and facilities for the segregation of lepers Patients with the maculo anesthetic variety especially when they have no demonstrable excoriated lesions in the nasal buccal or pharyngeal mucosae need not generally be strictly segregated but they should be required to take all precautions against contamination of others Long continued association with the nonleprous must be avoided rooms bedding wearing apparel cooking utensils etc must be used only by the patient all precautions being carried out just as in pulmonary tuberculosis

Many remedies have been used nearly all of them unsuccessfully with one exception namely *chaulmoogra oil* and its derivatives

Pure chaulmoogra oil may be administered *per os* in doses of from 5 to 60 drops three *times daily it may* be taken with a lump of sugar or mixed with milk or Vichy water Some patients bear it well in others it causes gastritis which necessitates cessation of the medication Many patients have however improved strikingly after long continued ingestion of this oil

The modern treatment and the most efficacious consists in subcutaneous and intramuscular injections *Mercado s formula* which was extensively employed by Heiser with very good results is as follows

Chaulmoogra oil	60 cc
Camphorated oil	60 cc
Resorcin	4 Gm

From 5 to 60 drops or even more of this mixture are injected into the gluteal muscles two or three times per week This often gives rise to considerable pain at the site of injection Currie and Hollmann claim to have had better results with

Iodine	1 Gm.
Oil of eucalyptus	8 cc
Camphor	2 Gm
Olive oil	147 cc
Chaulmoogra oil	150 cc

mixed in the order given using heat The maximum dose is 10 cc, given intramuscularly once a week

Apparently the most promising results thus far obtained have been from the use of the *fatty acids of chaulmoogra oil* Hollmann and Dean, in the course of their investigations in the Hawaiian Islands have for some years been administering the ethyl ester of the fatty acids of the oil with very promising results A large proportion of their patients have been helped, and a considerable number apparently cured—that is cured in the sense that lesions become undemonstrable and bacteria findings negative This product is on the market and may be obtained in large cities It is injected into the gluteal muscles twice a week in doses ranging from 10 drops to 1 drachm Treatment must be continued over prolonged periods—two three even five years—with intervening periods of rest

Fortnightly determinations of the sedimentation rate should accompany chaulmoogra therapy and when the rate is high treatment should be temporarily omitted

Treatment by means of fever therapy is now in the experimental stage

Collier and McKean have reported experiments with diphtheria antitoxin and diphtheria toxoid in patients with repeated lepra reactions As controls a number of similar patients were given injections of tetanus antitoxin and several others received antivenom The following beneficial results have been noted in approximately 120 patients treated by this method immediate reduction of leper nodules plaques and tuberculoids rapid improvement in leper reactions usually with lasting effects return of sensations to some previously anesthetic areas reduction of enlarged nerves particularly the ulnar nerves general physical improvement and fragmentation and granulation of the bacilli

Unfortunately the favorable results reported by Collier and McKean have not been confirmed by other investigators who have employed Collier s therapy on large

This variety of leprosy is more insidious and more protracted than nodular leprosy Death often results from complications in volving the liver and kidneys or from malnutrition and exhaustion

Recently the application of the allergic concept in infectious diseases has contributed to our knowledge of the causes of "tuberculoid' forms of leprosy with their relative *paucity of bacteria These were first* observed and interpreted by J Jadassohn (1898)

Mixed Type —Combinations of the symptoms of nodular and maculo anesthetic leprosy *are frequently encountered* and constitute the syndrome of the so called mixed type' The predominating lesions are usually of the nodular type in the earlier stages but later assume the symptoms characteristic of nerve involvement

Diagnosis —An advanced case of leprosy cannot be mistaken for other diseases but in the prodromal stage diagnosis is attended by great difficulties The patient especially if he comes from a region where the disease is endemic, should be stripped and examined in a good light Mottling and yellowish brown discolorations of the skin associated *with areas of hyperesthesia* anesthesia and paresthesia should excite suspicion The following changes should be carefully looked for thickening of superficial nerve trunks, thickening of the ear lobes and supra orbital regions loss of eye brows, nodules and deformities of the nails atrophy of the muscles and nasal pharyngeal and laryngeal lesions The earlier erythematous patches sometimes resemble *erythema multiforme* but are of longer duration there is no sensation of burning or smarting on the contrary the lesions are often anesthetic Nodular leprosy sometimes simulates *syphilis* but the duration of the syphilitic eruption is much shorter The history of a primary lesion and secondary eruptions together with evanescent lesions of the buccal mucosae should be taken into consideration hyperesthesia anesthesia and paresthesia are lacking The *Wassermann reaction* is frequently positive in nonsyphilitic lepers affected with nodular leprosy A recently published modification of the test perfected by Kolmer seems destined to become of practical use in the laboratory *differentiation* of the two diseases The *bacteriologic diagnosis* is of course the scientific method of differentiation, in leprosy, smear preparations should be made from the nasal and buccal secretions, *from the surface of ulcers* and excoriations and even from the serum of a curetted papule, in an attempt to find the specific bacteria In patients with suspected syphilis search should be made for *the Spirochaeta pallida* in the secretions of moist lesions, the serum of curetted papules or in the fluid of aspirated lymph nodes The result of the Wassermann test is significant In both diseases microscopic examination *of sections of the tissue is often* decisive The therapeutic test in syphilis is of great value

Certain manifestations of *lupus vulgaris* of *mycosis fungoides* of the *hemorrhagic sarcoma* of Kaposi of *vitiligo* of the comparatively rare *annular syphilids* and of a few other eruptions characterized by rings gyrate and polycyclic figures are sometimes apt to cause confusion in differential diagnosis but in the great majority of instances in which these diagnoses might obtrude themselves the actual difficulties encountered are more imaginary than real

In syringomyelia which is apt to be confounded with leprosy, there is an alteration of the pain and temperature sense without loss of tactile sensibility—the so called dissociated anesthesia , the occurrence of pain *less whitlow* and various *trophic distur*bances in the absence of cutaneous manifestations is evidence of this disease and not of leprosy

Prognosis —Until the last few years the outlook for the leper has always and everywhere been regarded as hopeless Despite the fact that some patients with spontaneous regression of symptoms and temporary freedom from lesions have been encountered the overwhelming proportion die wretchedly Recent investigations of the chemotherapeutic properties of the ethyl esters of chaulmoogra oil have however changed the prognosis from 'very bad to hopeful Reports of cures are now appearing in the *literature*

Patients suffering from the less virulent maculo anesthetic variety are apt to live for one or more decades in comparative comfort *depending upon environment nursing by*

countries bovine herds remain heavily infected and the incidence is estimated as high as 40 per cent in Great Britain

Incidence in Man —No branch of the human race has escaped the touch of tuberculosis and this is true in whatever part of the world man abides The severity of its effects however varies greatly in different communities Although the infection is very common most people survive The occurrence of infection mortality and morbidity therefore must be analyzed separately Formerly in most communities almost all adults reacted to the tuberculin test and this is still true in some sections In the United States however there has been a decided decline in the rate of infection and it is estimated now that 50 per cent or less of the population would react In Detroit for instance Douglas and Harmon in 1938 reported the following results of the tuberculin skin test among the population of that city

Age	*Number tested*	*Percentage positive*
0– 9	20 585	5.9
10–19	22 441	18.9
20–29	21,304	38 0
30 and over	34 862	44.3
Not stated	222	50.2
Total	99 414	29.2

In congested urban centers infection is more prevalent as indicated by the observations of Lincoln Raia and Gilbert in the wards and clinic of Bellevue Hospital between 1930 and 1936 Among 11 136 children tested reactions were elicited in 0 7 per cent of those tested between birth and six months of age 5.3 per cent between six and twelve months 10 per cent between one and two years 15 1 per cent between two and four years 18 1 per cent between four and six years 23.5 per cent between six and eight years 26.9 per cent between eight and ten years 32 6 per cent between ten and twelve years Among 149 744 college students in the United States according to the 1941 report of the American Student Health Association the incidence of tuberculin reactors was 20 7 in 100

Some of these figures are misleading because of the inadequacy of the dose of tuberculin Carnes studies of autopsies performed in Baltimore during 1938–1940 indicated according to him that 90 per cent of the adult population of that city has been infected Some he thinks are so lightly infected that they may lose their tissue hypersensitivity and fail to react to the tuberculin test In a similar study in the Washington County Hospital Hagerstown Maryland during 1938–1940 Lande and Wolff found tuberculous lesions in 48 4 per cent of 128 subjects

Mortality from the disease also varies greatly in different parts of the world Before the outbreak of World War II it was less than 50 per 100 000 population per year in Denmark Netherlands Australia New Zealand and the United States In England and Wales Italy Germany and Sweden the rate was between 50 and 100 per 100 000 In Japan and Finland it approximated 200 and in Chile Puerto Rico and the Philippines it exceeded 250 A rather steady and striking decline in mortality had been observed for many years in various countries In the United States the rate per 100 000 per year declined from 202 in 1900 to 160 in 1910 114 in 1920 71 in 1930 and 44 4 in 1941 However the present war has brought a reversal of this trend in England Germany and France and probably in many other countries In England where the death rate has risen 13 per cent the increase of tuberculous meningitis among children has been especially high In this country tuberculosis now stands seventh among the leading causes of death but it is still the leading cause between the ages of fifteen and forty five Death is due to the pulmonary form of the disease in about 91 per cent of all cases and to nonpulmonary or generalized forms in 9 per cent

Morbidity is variously estimated In most communities approximately 2 new cases of the disease are reported each year for every death It is generally estimated that there are approximately 5 active clinical cases for each annual death In the United States therefore with its 59 251 deaths in 1941 the estimate would be approximately 296 000 active cases Case-finding surveys among apparently healthy people disclose about 2 per cent of the adults harboring lesions recognizable in the roentgenogram Approximately one half of these are usually found to be active or potentially active

groups of lepers In the overwhelming majority of cases no beneficial effect was demonstrable In patients who appeared to be benefited improvement was negligible and ephemeral

Cutaneous lesions—plaques nodular infiltrations and ulcerations—often respond favorably to exposure to the roentgen ray Infiltrated lesions and deep seated ulcers should be treated with filtered rays, the average dose is 300 r filtered through 3 mm of aluminum screen once every three or four weeks Radium should be employed for lesions in the mouth and about the eye Antiseptic and general surgical procedures are necessary in advanced cases Frequent hot baths with sodium bicarbonate dissolved in the water are beneficial Change of climate and the use of a good tonic such as a combination of iron quinine and strychnine are at times helpful

Fig 26—A well developed case of nodular leprosy in a native of Odessa, Russia The patient was sixty five years old had been in America for twenty five years and had noted her first lesion about five years ago (J A Fordyce)

TUBERCULOSIS

Definition—Tuberculosis is an infectious disease caused by the tubercle bacillus Tuberculosis is a widespread disease of man and animals uniformly fatal in some seldom if ever in others acute and generalized in some individuals chronic and localized in others pathologically the disease is characterized by the development of tubercles and diffuse inflammatory lesions

History—Archeologic discovery of skeletons bearing the marks of tuberculous lesions indicate that the disease existed in remote antiquity Described in the earliest medical records it was called consumption or phthisis because of its most conspicuous external feature wasting Long considered to be of many varieties and origins the unity of the disease was first recognized by Laennec The correctness of his conceptions was disputed by many including Virchow and was not universally acknowledged until Koch in 1882 isolated the specific organism and reproduced the disease experimentally The avian type of bacillus was isolated in 1890 by Maguccı and the bovine type in 1898 by Theobald Smith

Distribution—Under certain conditions fish amphibians fowls and animals may develop tuberculosis although in their wild state these classes are not very susceptible Animals in captivity sometimes fall easy prey to the disease Among domesticated animals it is seldom observed except in cattle swine and gallinaceous birds In the United States an active plan of eradication of tuberculosis from cattle has been highly successful so that the incidence is now well under 1 per cent even less among swine In many

rate in old men as compared with old women may involve similar forces

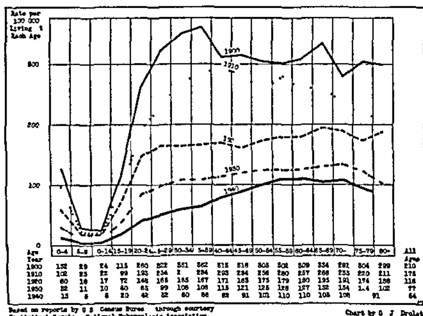
Allergy and Immunity.—These factors which begin to assert themselves shortly after the development of the first lesion modify subsequent reactions Koch demonstrated that an animal previously inoculated with tubercle bacilli slowly develops an indolent and usually nonulcerating lesion at the site of inoculation and dies with progressive and generalized tuberculosis after the lapse of a few months Within a few weeks after the inoculation the tissues for the first time become sensitive to tuberculin This altered reaction is known as tissue hypersensitivity a form of allergy Similarly Koch found that a second inoculation of bacilli into the skin of a previously infected animal produces a lesion which behaves differently from the primary The local reaction is rapid and intense with a tendency to abscess formation ulceration extrusion of the necrotic matter and subsequent healing Dissemination of bacilli from this focus through the lymph and blood streams is much slower and less severe This the Koch phenomenon is a manifestation of allergy (tissue hypersensitivity) and of acquired relative immunity the mechanics of which has been identified only partly Weakly concentrated humoral antibodies may be demonstrated Phagocytosis and the deposition of fibrin barriers at the site of the lesion are accelerated and intensified If the primary infection was not overwhelming or was accomplished with an attenuated strain of bacilli the animal now may survive the effects of reinfection for many months In the human being tissue hypersensitivity which usually develops within three to six weeks after the first infection helps to explain certain intense inflammatory reaction such as serous pleurisy Acquired immunity which is never absolute seems to develop much more slowly and to be maintained despite the subsidence of tissue hypersensitivity ('nathergic immunity Birkhaug) The latter judged by the tuberculin test sometimes fades and disappears as lesions heal but it is not proved that acquired immunity is lost entirely

Heredity.—The superior resistance of certain races such as the Jews suggests that hundred of years of experience with tuberculosis results in the elimination of the susceptible and the survival of relatively resistant members It has been intimated that specific immunity may be inherited to a degree but this has never been proved The evidence is more suggestive that some racial stocks have a stronger or weaker natural resistance—a genetic character

Constitution and Race.—Clinicians have often described types of people thought to be susceptible to tuberculosis *e g* the asthenic thin skinned silken haired Titian blond Recent statistical studies such as that of Wolff and Ciocco focus attention on the importance of constitution with regard to susceptibility and resistance Kallmann and Reisner studying monozygotic and dizygotic pairs of twins found that the chance of developing tuberculosis increases in direct proportion to the degree of blood relationship to a tuberculous case Lurie has been able to breed families of rabbits in which the greatly varying resistance is a function of their genetic constitution The higher mortality among Negroes in many parts of the world is ascribed by some entirely to poor living conditions However the striking tendency of the lesions to undergo caseation rapidly and the greater liability to lymphohematogenous dissemination of the infection indicates that there is a real constitutional peculiarity in this race In the United States the tuberculosis death rate for Negroes is three to five times that among whites in 1910 11 per cent of all deaths from tuberculosis occurred in colored people while in 1940 the proportion was 26.3 per cent indicating a less rapid decline of mortality among Negroes as compared with whites

Age and sex influence the behavior of the disease whether this originates in a recent primary infection or in a recent extension from remotely established lesions Generalized tuberculosis is much more common in early childhood Chronic pulmonary tuberculosis characteristically begins to appear in the second and third decades Those who have lived to the fourth decade without the appearance of a pulmonary lesion seldom develop the disease Figures 27 and 28 portray the mortality experience with relation to sex and age

Epidemiology —Since man may be infected by the human or bovine type of the bacillus the source is usually traced to another person with tuberculosis or to a tuberculous cow Contaminated milk is seldom implicated in this country but in others it is considered responsible for much human disease especially abdominal tuberculosis In Scotland it has been estimated that as many as 8 per cent of the cases of pulmonary tuberculosis are due to the bovine type of bacillus and the incidence is higher in other lesions such as tuberculous lymphadenitis osseous tuberculosis and tuberculous meningitis The more common source of infection is the human case of tuberculosis with pulmonary cavities draining through the bronchi and giving rise to sputum laden with organisms Other lesions such as superficial tuberculous sinuses may constitute sources and the possibility of transmission through contaminated urine or feces occasionally has to be considered The means of transmission however is usually contaminated air inhaled by persons in the vicinity of the sufferer Direct mouth to mouth transmission may occur particularly in the case of nurslings As would be expected therefore many new cases of tuberculosis are discovered near the abodes of people previously afflicted In this sense the disease is frequently familial or household and it is also somewhat more prevalent among the personnel of hospitals or other institutions caring for tuberculous patients Infection has been shown to be almost inevitable among young children who have such opportunities in the home for close contact with the 'open case' usually in an adult Intimacy and frequency of contact favor heavy and repeated infection thus more serious disease



Bacteriology —The tubercle bacillus (*Mycobacterium tuberculosis*) exists in three types the human (*typus humanus*) the bovine (*typus bovinus*) and the avian (*typus gallinaceus*) Man may be infected by the human or bovine types seldom by the avian type Animals are infected most often by the bovine type This varying pathogenicity may be used to help identify the type Thus cavia are susceptible to infection by the bovine and human types but not the avian rabbits are susceptible to the bovine and avian, much less to human fowls usually are susceptible only to the avian The bacillus is a rod shaped organism distinguished particularly by its acid fastness to stains Granular forms have been recognized but the existence of a virus stage is not generally acknowledged The bacillus grows slowly and aerobically on various culture media R J Anderson particularly has studied the chemistry of the bacillus which is made up mainly of lipids waxes polysaccharides and proteins There is no capsule While the organism is tenacious of life and may survive many months in the dark or when refrigerated, it survives only a short time in rooms well supplied with unfiltered daylight (C R Smith) and it is killed by boiling in water for two minutes or pasteurization at 60° C

Organisms isolated from human cases are with rare exceptions virulent in guinea pigs The pathogenicity may be attenuated by prolonged growth on certain artificial media such as the bile treated potato medium of Calmette and Guerin and Smithburn has succeeded in altering this property merely by varying the hydrogen ion concentration of the medium

Etiology —*Man is relatively resistant* to invasion by tubercle bacilli Infection is common but less than 10 per cent of all those infected die of the disease This bespeaks a native resistance which as a rule *is highly effective* Its precise nature is not understood and it is difficult to distinguish it from the numerous other factors which influence the course of the infection Natural resistance varies with age Young infants may go on to develop generalized tuberculosis soon after the first infection and the case fatality rate at this time of life, calculated on the basis of the number infected is higher than at any other age despite the fact that only about 1 per cent of all deaths in the United States before the age of five are due to tuberculosis The mortality rate is generally low between the ages of five and adolescence when there is an abrupt rise reaching its peak in females in the early twenties somewhat later in males This suggests strongly that biologic influences associated with puberty alter natural resistance The relatively high death

tendency before the discovery of insulin Pulmonary tuberculosis is a frequent com plication of congenital pulmonic stenosis but when present usually runs a relatively mild course in association with mitral sten osis Tuberculous patients frequently with stand pneumococcal pneumonia well unless the functional reserve has been almost de- pleted previously Suppurative pneumonia or abscess however, may lead to breaking down an arrested tuberculous focus and sub sequent extension of the infection from it

Morbid Anatomy—The inflammatory reaction to infection by the tubercle bacillus times termed a productive tubercle because of its tendency to proliferate add to its mass and displace surrounding tissues Either may be progressive or retrogressive Progression is evidenced by changes in the extent and character of the lesion The cen tral elements where as a rule bacilli are most heavily concentrated become coagu lated undergo caseous degeneration and finally liquefaction Not only the lesion itself but also the invaded tissues are involved in the destruction Because of its increasing tension the abscess may dissect a path through surrounding structures but is prone

varies morphologically from the tubercle to a diffuse exudation of cellular and humoral elements The isolated tubercle made up of giant cells lymphocytes and so called epi thelioid cells represents a relatively mild reaction resembling that to a foreign body Diffuse inflammation consists chiefly of plasma fibrin leukocytes large phagocytic cells and sometimes erythrocytes Such dif ferent types of lesions may develop simul taneously in the same or different tissues or may exist side by side Generally speaking the exudative lesion so called because it is an exudation of inflammatory products into tissue spaces is more acute sometimes in tensely so The epithelioid tubercle is some to find an outlet through ulceration Through this vent then the liquefied mat ter is discharged and characteristically there is left behind a fistula which may be perma nent or occasionally may heal as granula tions proliferate from the base of the ulcer

Healing of tuberculous lesions occurs mainly by resolution absorption and fibrosis Resolution operates chiefly in exu dative lesions and is indicated by the gradual disappearance of serous and cellular elements first at the periphery proceeding centrally A central caseous focus if it is not sloughed out by ulceration may become in spissated slowly and later infiltrated by mineral salts chiefly calcium in time the

Physiologic and Psychologic Influences — Pregnancy is recognized in some women to activate pulmonary tuberculosis Impaired nutrition particularly when there has been a deprivation of essential vitamin and mineral elements may lower resistance The current increase in tuberculosis deaths in the war torn countries appears to be due in part to the limitation of food supplies there was a similar rise in first World War Psychologic influences usually are not conspicuous although one gets the clinical impression that the unstable emotional person is less resistant There is some evidence is greatest *Occupation* which is a good index of social economic status illustrates this strikingly The death rate is highest among unskilled laborers and lowest among those in professions including physicians A specifically dangerous occupation with relation to tuberculosis is that which involves exposure to silicious dust This hazard exists in many industries and the death rate from tuberculosis among the employees sometimes is six to eight times that among other comparable groups Meteorologic conditions have an influence especially upon labile tuberculous lesions and help to explain the

Fig 27 —Female tuberculosis death rate by age years 1900 1910 1920 1930 1940 United States (expanding) death registration area

that tuberculosis is more likely to develop in schizophrenics The death rate is usually high in institutions for the mentally ill but this seems now to be ascribable to intimate exposure and to be largely correctible by isolating the infectious cases

Environment —Geographic location alone does not seem to be a major influence Tuberculosis is a serious problem both in the Alaskan Indians and in Puerto Ricans Social economic and occupational factors are much more important Ignorance poor housing and overcrowding all are recognized as powerful evils Haven Emerson points out that in cities tuberculosis is prevalent in those sections where nonpayment of taxes trend to activation in the late winter and spring

Trauma —Previously healthy traumatized tissue is not liable to be invaded by tuberculosis except by direct extension from an immediately adjacent lesion Direct traumatization of tuberculous tissue however may be aggravating In the case of pulmonary tuberculosis occasionally a severe trauma of the chest may result in such manifestations as hemoptysis bronchogenic dissemination of the infection or pleural rupture with secondary empyema

Intercurrent Disease —Diabetes if uncontrolled especially in young people predisposes to serious tuberculosis a conspicuous

a walnut but usually the size of a pea It is situated most often near the pleura in a lower lobe or the lower part of an upper lobe usually the right From pathologic evidence and a great deal of experimental work it has been shown that tubercle bacilli soon escape from this initial focus and traverse the lymphatics to the bronchopulmonary and tracheobronchial nodes where secondary lesions develop This combination of pulmonary focus and tributary lymphadenitis (occasionally with intervening tubercles) is called the primary complex Commonly the lesions become arrested at this point and undergo regressive changes leaving only small fibrous or calcified residues which may remain permanently

Occasionally the disease is progressive from the very start particularly in infants and young children While the focus in the pulmonary parenchyma may progress it is much more common to find the continuing changes in the lymph nodes of the mediastinum These may enlarge so as to fill the mediastinum and compress contiguous structures and occasionally a caseous node may ulcerate into the trachea or a large bronchus there to discharge its contents However a more common sequence is contamination of the blood stream by direct ulceration of a vessel or much more often through the escape of bacilli by way of the lymphatics into the innominate vein Such mechanisms account for the high proportion of deaths from generalized tuberculosis among infants If the primary infection is postponed until later in life this tendency appears to be less striking *e g* in young adults the occurrence of large lymphatic lesions and of blood stream dissemination is much less frequent than it is in infants Exceptions to this rule are observed especially in young adult Negroes

Lymphohematogenous Dissemination — In young children there is pathologic evidence to suggest that infection of the blood stream may occur at almost any period of development of the primary lesions until they become encapsulated (postprimary dissemination) and occasionally during their reactivation after many months or years of latency

The behavior of lymphohematogenous disseminations depends first on the point of emergence of the invading organisms into the blood stream A tubercle sloughing into a pulmonary vein liberates bacilli which quickly gain access to the systemic arteries and immediately are distributed widely through the body in the returning venous stream those which have not been arrested elsewhere may lodge in the lungs More often however especially in infants the point of emergence is a caseous mediastinal lymph node whence the bacilli shortly enter the venous blood Thus the lungs again suffer the heaviest onslaught and if most of the bacilli should be screened out here only a minority may find their way into the arterial stream for general distribution These differences help explain variations in the picture of hematogenous tuberculosis such as the finding of lesions in the lungs when there are only few or none to be discovered in other parts

Bacilli entering the blood stream are rather promptly removed and apparently arrested in the tissues if one interprets correctly the usual failure to recover the organisms by blood culture However the frequency of blood stream invasion even among those who never develop tuberculosis in a clinical form is attested by the common finding at autopsy of old encapsulated foci in the liver kidneys spleen lymph nodes and other tissues

The great variation in the number and severity of hematogenous lesions is related somewhat to the mass of the infecting dose, its physical suspension and the rate or repetition of its discharge Abrupt liberation from a liquefied caseous focus of myriads of tubercle bacilli which become finely dispersed in the blood may be the initiation of acute generalized miliary tuberculosis in contrast the escape of a single clump may result in only a single lesion at some distant point as in the kidney Numerous bacilli collected into a relatively few clumps and so deposited at various sites may produce the picture of subacute generalized tuberculosis in which many of the lesions are larger than miliary and become grossly caseous When bacilli are liberated in small doses at varying intervals of time the result is the establishment of hematogenous foci of varying age and chronicity as indicated by the

caseous mass especially if it is only several mm in diameter may be entirely transformed through a chalky stage into a hard calcareous deposit If this becomes sterile it may undergo true ossification More often the transformation is incomplete and a partially calcified cheesy collection remains in which tubercle bacilli may remain viable many years *As implied caseous collections* of material size seldom become absorbed completely but constitute infectious foci *from which disseminations may occur* after a longer or shorter period of latency Such latency depends largely on the character and intactness of the enveloping fibrous capsule which gradually forms This at first is tuberculous granulation tissue but eventually may be transformed into thick connective tissue Resolution does not necessarily antedate fibrosis The gray tubercle for instance may be transformed slowly into a fibrous mass perhaps with only a minimal caseous center Eventually all tuberculous elements may disappear leaving only a scar without marks to identify its specific origin In other circumstances stimulated presumably by the slight but persistent diffusion of toxins from the necrotic center of a lesion fibrosis may extend centrifugally into relatively healthy tissue, the organization of exudate within undestroyed alveoli has been designated carnification Fibrosis often increases in density and thickness until it acquires an almost cartilaginous *consistency Its shrinkage produces* mechanical effects which vary with the structure involved There are retractions constrictions and distortions and sometimes these lead to profound functional disability

Once a liquefied tuberculous lesion has sloughed and communicates with a cutaneous or mucous surface secondary infection with pyogenic bacteria may occur contributing toward chronicity

Modifying Influences—The properties of tuberculous lesions while essentially identical are influenced by a great many factors One example is the nature of the tissue attacked The skin is relatively very resistant and seldom infected from without Compact organs like the liver or spleen are seldom involved in destructive tuberculosis but the contrary is true of the lungs It is easier to infect the lungs than the mucosa of the nose mouth or intestine, this difference appears related in part to mechanics such as ciliary action and the *movements* of mucus or ingested food which prevent long contact of the bacillus with the mucosal *surface This has been cited to help* explain the predilection of the ileocecal region for tuberculous invasion since intestinal *motility is slower here than above* The behavior of a lesion often is conditioned by opportunities of localization thus diffuse *inflammation* of the pleura with serous exudation occurs much more often when the visceral and parietal layers are separated as by artificial pneumothorax An obvious explanation is that this separation prevents the fibrinous agglutination of the inflamed surfaces which usually serves to confine the process Other relationships are recognized such as the proximity of involved parts thus a common complication of tuberculous salpingitis is pelvic peritonitis Similarly vascular relationships often determine not only the paths of transport of the infection but also the sites of implantation

Pathogenesis—Almost any tissue may be successfully inoculated with tubercle bacilli and the primary lesion has been observed in a number of sites including the eye the finger the prepuce (following circumcision rites) the tonsil the intestine and the lung A relatively high proportion of abdominal tuberculosis occurs in countries where there are great chances of infection by the *ingestion of contaminated* raw milk However the pathologic investigations *of* Ghon and others following him have shown that the common portal of entry is the lung and the common means of infection inhalation Presumably a few tubercle bacilli may be carried into the mouth alimentary canal nose trachea or bronchi without causing lesions indicating prompt and complete effectiveness of the physiologic defenses It may be reasonable even to assume that lethal phagocytosis may occur sometimes when the organism has reached an alveolus Under suitable conditions however inhaled bacilli reaching the pulmonary alveoli result in a lesion which when identified usually is of an exudative nature a small *focus* of bronchopneumonia As Ghon first described this primary focus is usually single varying in size from that of a hemp seed to that of

a walnut but usually the size of a pea It is situated most often near the pleura in a lower lobe or the lower part of an upper lobe usually the right From pathologic evidence and a great deal of experimental work it has been shown that tubercle bacilli soon escape from this initial focus and traverse the lymphatics to the bronchopulmonary and tracheobronchial nodes where secondary lesions develop This combination of pulmonary focus and tributary lymphadenitis (occasionally with intervening tubercles) is called the 'primary complex Commonly the lesions become arrested at this point and undergo regressive changes leaving only small fibrous or calcified residues which may remain permanently

Occasionally the disease is progressive from the very start particularly in infants and young children While the focus in the pulmonary parenchyma may progress it is much more common to find the continuing changes in the lymph nodes of the mediastinum These may enlarge so as to fill the mediastinum and compress contiguous structures and occasionally a caseous node may ulcerate into the trachea or a large bronchus there to discharge its contents However a more common sequence is contamination of the blood stream by direct ulceration of a vessel or much more often through the escape of bacilli by way of the lymphatics into the innominate vein Such mechanisms account for the high proportion of deaths from generalized tuberculosis among infants If the primary infection is postponed until later in life this tendency appears to be less striking *e g* in young adults the occurrence of large lymphatic lesions and of blood stream dissemination is much less frequent than it is in infants Exceptions to this rule are observed especially in young adult Negroes

Lymphohematogenous Dissemination — In young children there is pathologic evidence to suggest that infection of the blood stream may occur at almost any period of development of the primary lesions until they become encapsulated (postprimary dissemination) and occasionally during their reactivation after many months or years of latency

The behavior of lymphohematogenous disseminations depends first on the point of emergence of the invading organisms into the blood stream A tubercle sloughing into a pulmonary vein liberates bacilli which quickly gain access to the systemic arteries and immediately are distributed widely through the body, in the returning venous stream those which have not been arrested elsewhere may lodge in the lungs More often however, especially in infants the point of emergence is a caseous mediastinal lymph node whence the bacilli shortly enter the venous blood Thus the lungs again suffer the heaviest onslaught and if most of the bacilli should be screened out here only a minority may find their way into the arterial stream for general distribution These differences help explain variations in the picture of hematogenous tuberculosis such as the finding of lesions in the lungs when there are only few or none to be discovered in other parts

Bacilli entering the blood stream are rather promptly removed and apparently arrested in the tissues if one interprets correctly the usual failure to recover the organisms by blood culture However the frequency of blood stream invasion even among those who never develop tuberculosis in a clinical form is attested by the common finding at autopsy of old encapsulated foci in the liver kidneys spleen lymph nodes and other tissues

The great variation in the number and severity of hematogenous lesions is related somewhat to the mass of the infecting dose, its physical suspension and the rate or repetition of its discharge Abrupt liberation from a liquefied caseous focus of myriads of tubercle bacilli which become finely dispersed in the blood may be the initiation of acute generalized miliary tuberculosis in contrast the escape of a single clump may result in only a single lesion at some distant point as in the kidney Numerous bacilli collected into a relatively few clumps and so deposited at various sites may produce the picture of subacute generalized tuberculosis in which many of the lesions are larger than miliary and become grossly caseous When bacilli are liberated in small doses at varying intervals of time the result is the establishment of hematogenous foci of varying age and chronicity as indicated by the

different sizes and different stages of caseation and healing In view of such manifold possibilities great variation must be expected and is observed in the clinical manifestations If the hemic invasion is not soon fatal (and usually it is not) lesions may progress where established and one result is isolated ulcerative tuberculosis of single organs In the kidney for instance the parenchyma may be destroyed and the infectious matter discharged through the ureter, may lead to invasion of the bladder Intermediate forms of more or less generalized or slowly developing hematogenous tuberculosis may be manifested by generalized lymphadenopathies exudates in one or more of the serous cavities and various forms of skeletal and visceral tuberculosis As stated the lungs are peculiarly open to attack because of their interposition between the smaller and greater circulations

J BURNS AMBERSON, JR

TUBERCULOSIS OF THE LUNGS

From the foregoing description it is seen that tubercle bacilli may gain access to the lungs in the inspired air through the blood stream or by direct extension from lesions in adjacent structures In fact infection may occur along several paths almost simultaneously since bacilli from the primary lesion acquired by inhalation infection may be liberated rather promptly into the lymphatics and speedily may reach the lungs again through the venous blood stream Pathologists have found in addition to the characteristic primary complex presumably hematogenous tubercles in the lungs of infants who have lived only several months Quite commonly however the primary lesions are arrested before much, if any hematogenous dissemination has occurred and this may be followed by permanent healing or by a period of latency during which the implanted infection is held in abeyance by enveloping *fibrosis* The latent period may last for many years after which old lesions in the lungs particularly those at the apices may become reactivated and go on to progressive ulcerative disease Similarly arrested lesions of the mediastinal lymph nodes or of some distant structure may become activated not only to cause local damage, but also to liberate tubercle bacilli freshly into the blood stream thus reinfecting the lungs Less commonly after an interval of latency, caseous lymphadenitis may ulcerate into a bronchus and through the resulting fistula discharge its highly infectious products into the lungs In adult life chronic pulmonary tuberculosis the most common form of the disease probably is initiated by one of these mechanisms especially the first mentioned more often than by any other Another alternative is exogenous reinfection by the renewed inhalation of tubercle bacilli and this is thought still by some to be the commonest

The *earliest evolution of chronic pulmonary tuberculosis* whatever may have been its origin is not often identified in the living patient Starting most often in late adolescence or early adult life the steps of progression are represented usually by direct extension of the lesion and by ulceration of its liquefied center, discharge of its contents into the bronchi and inhalation of the infectious pus into healthy alveoli immediately adjacent or in some more distant section (transbronchial or bronchogenic dissemination) These changes at first may be confined to microscopic areas Ulceration may be minute but the small quantity of liquefied matter liberated may contain numerous tubercle bacilli which if lodged in healthy alveoli are likely to cause an acute limited exudative reaction bronchopneumonic in character Depending on its size this secondary lesion also may be occult or it may be visible by x ray examination It may be absorbed it may become temporarily latent or it may progress immediately As a rule progression involves a repetition of the same processes of peripheral extension central caseation liquefaction *ulceration* and bronchogenic extension There is a succession of such steps until the disease becomes clinically manifest While the essential mechanisms are almost constantly the same the way of their operation varies greatly Thus the steps may succeed each other quickly in a space of a few weeks or months or only after long intervals of apparent quiescence and partial healing one renewed attack may be mild and abortive another acute overwhelming and fatal As a rule each leaves some permanent damage

Some of the influences responsible for these variations may be understood easily A small productive epithelioid tubercle does not break down and ulcerate readily If so it is a slow process with the discharge of small quantities of bacilli leading commonly to very gradual extension of the disease into surrounding areas A small exudative lesion on the other hand tends to slough early into the bronchus and to discharge larger quantities of bacilli consequently causing more acute and pneumonic types of secondary lesions Not only the quantity but also the concentration of bacilli liberated through the ulcerous tract into the bronchial tree has an important modifying influence If the discharge is slight and bacilli are few the secondary lesions if any are more likely to be of an isolated nodular and productive character But if a tuberculous abscess containing 1 cc., more or less of liquid pus suddenly breaks into a bronchus the huge dose of organisms which then may gain access to surrounding alveoli causes a most intense acute pneumonic reaction Once the ulcer or cavity has formed the fluidity of the discharge helps to determine the likelihood and seriousness of secondary lesions A coherent mucopurulent mass passing through the bronchi usually is carried intact to the trachea and may be expectorated readily by coughing but thin fluid pus gravitates easily into the smaller air passages This physical factor alone accounts largely for the greater liability to acute extension of the disease during and after a hemorrhage The posture of the patient when infectious matter from a cavity is aspirated may help direct the flow and determine the site of new lesions This is illustrated by certain results of pulmonary hemorrhage during which the patient usually lies supine in bed the subsequent tuberculous pneumonia is found most often in the posterior and dependent parts of the lower lobes where the inhaled baciliferous blood gravitated Since during sleep or unconsciousness fluid matter tends to accumulate in pulmonary cavities and protective mechanisms like the cough reflex are less active there is reason to believe that transbronchial spread of infection often occurs as the patient changes his position allowing the pus to drain into connecting bronchi

The *degree of immunity* acquired during the previous course of the disease and inborn constitutional resistance have a decided influence Hypersensitivity with low immunity apparently makes for acute inflammatory pneumonic lesions, high immunity and resistance for chronic localized productive lesions Massive infection however, overwhelms high resistance

As pulmonary tuberculosis runs its varied course the pleura almost inevitably becomes involved The nature of the pleurisy depends greatly on the underlying parenchymal reaction varying from a mild local fibrinous and later fibrous process to an acute diffuse and serous inflammation In chronic pulmonary disease the infrequency of serious and fatal hematogenous dissemination as compared with the first infection in childhood is striking By contrast however the frequent ulceration of chronic pulmonary lesions results commonly not only in a spread through the bronchial system but also in contamination of the mucous surfaces of the respiratory and gastro intestinal tracts Serious complications from this mechanism are observed often as tuberculosis of the larynx and of the intestine less commonly lesions are found in the middle ear to which bacilli may be carried through the eustachian tube in the tongue in the lips or in the buccal or gingival mucosa

Clinical Course in Relation to the Pulmonary Lesions—Tuberculosis must be visualized as a moving dynamic process and symptoms must be recognized as having a definite relationship to the changing lesions otherwise a satisfactory understanding of the disease can hardly be acquired Individual patients vary in their toleration of the effects of the disease Sensitive highly strung people are more aware of minor disturbances while the rugged and phlegmatic may not be conscious of mischief until the disease is far advanced The symptoms of toxemia are principally general and depend on the rate and degree of absorption of toxic products from the pulmonary lesions into the lymph and blood streams Localized toxic effects such as neurotropic manifestations are less conspicuous clinically

Profound toxemia seldom is manifest until the early lesions have ulcerated and discharged their contents giving rise to sec-

ondary extensions If however the toxic and liquefied necrotic centers of lesions are expectorated without incidental transbronchial spread of the infection general symptoms may abate This explains certain clinical disparities such as a patient gaining weight and experiencing a diminution of fever while pulmonary cavities are enlarging Ordinarily, toxemia lessens sooner than the local symptoms but this depends on the patient s activity When he is quiet circulatory interchange between the lesion and the tissue fluids is less than it is when he is exercising strenuously Manifest toxemia usually subsides before the pulmonary lesions become fibrosed Consequently constitutional symptoms are unreliable as indicators of the degree or rate of healing Local symptoms are related mainly to the effects of ulceration of pulmonary lesions Cough and expectoration then are due to the discharge of mucopurulent and purulent matter Similarly hemorrhage is seldom observed except in the presence of ulceration and excavation Pain may antedate these local symptoms if the pleura becomes involved early

While the *earliest discoverable lesion* in the lungs is usually of an exudative bronchopneumonic character there may be little or no manifest toxemia from it Several successive bronchogenic extensions may occur before the effect is sufficient to be subjectively apparent It is for this reason that patients usually do not become wholly aware of symptoms of pulmonary tuberculosis until it has progressed beyond the stage of excavation From this point the disease may come into the open so to speak and may be easily recognized as it runs the course of an acute or chronic disease with many intermediate gradations

Acute tuberculous pneumonia with its stormy clinical manifestations developing more often in the young than in the aged and more often in Negroes than in whites usually is initiated by the discharge of enormous numbers of bacilli from a cavity near the summit of the lung occasionally from a caseous lymph node which has ulcerated into the trachea or bronchus The reaction to such a mass of infection is prompt and marked by a rapid and widespread inflammatory exudation In other cases dissemination of the infection through the lungs may be slow and scanty and the secondary extensions may be only slight or *moderate, with a decided tendency to limitation and fibrosis* Local symptoms such as cough and expectoration may be mild and *the toxemia may be chronic* but not severe The progressive fibrosis of the lungs and the accompanying emphysema developing gradually *through many years may lead to* increasing respiratory difficulty, chronic malnutrition and impairment of working ability *Very commonly however the disease progresses* steadily or intermittently with greater intensity Each extension may give rise to *subacute constitutional symptoms* resembling those of grippe but each may be followed by prompt or gradual convalescence In such cases then, a combination of lesions of all phases may be seen such as a contracted scar at an apex a cavity below this and areas of bronchopneumonia elsewhere In the long standing cases the history and the morphologic pattern of the lesions as depicted in the x ray film may enable one by inference to judge their mode of development In summary, then it may be said that the severity of the secondary extensions from the early lesions their repetition and the intervals of time between them are the factors fundamentally determining the clinical course In time practically all progressive pulmonary tuberculosis becomes bilateral because of the facility of spread through the bronchial system In some cases bilateralization occurs promptly after the first ulceration The characteristic direction of spread is from above downward but it is not rare to identify an early infiltration in a lower lobe with secondary extensions from this toward the apex

The lungs commonly participate in *disseminated hematogenous tuberculosis* and *may bear the large brunt of the attack* In the acute generalized miliary form the lungs are quickly and uniformly seeded with small tubercles which as a rule do not ulcerate because death intervenes If dissemination is of lesser intensity the lungs may be studded uniformly with a few or a moderate number of tubercles Since the patient may survive then for considerable time perhaps years further local evolution of the lesions may occur Cavities may *develop in one* lung or simultaneously in both and from

this time on the course may be that of bronchogenic extension Occasionally the infection of the lungs through the hematogenous route is very mild although widespread The tubercles then may organize with little or no ulceration giving rise to a form of chronic pulmonary fibrosis and emphysema which eventually may be manifested chiefly by symptoms of functional respiratory impairment

Onset of Pulmonary Tuberculosis—As indicated in the preceding paragraphs the mode of onset varies greatly according to the sensitiveness of the patient and the behavior of the pulmonary lesions Commonly the first manifestations lag behind the actual appearance of the lesions and this *subclinical interval* may be short or long

Acute tuberculous pneumonia may produce the first clinical symptoms This form is uncommon although not rare being observed most often in young people in Negroes and in debilitated old people A preexisting excavating lesion is almost always present but the patient may not have been impressed with the mild symptoms caused by it The acute attack may appear to be precipitated by exposure to inclement weather by a common cold by severe sunburn by a hemoptysis or by some trivial influence The patient may experience chilliness prostration pain in the chest and fever usually moderate but sometimes severe and sudden The fever may rise quickly to 104° or 105° F and the pulse rate to 100 or more per minute The breathing is quickened at first (twenty to thirty respirations per minute) later becoming labored and more rapid as the lungs become further engorged it is seldom noisy or grunting A feeling of congestion in the chest increases and the lips and extremities become slightly or moderately cyanotic The cough may not be severe at first and may be productive of only a few cubic centimeters of mucopurulent sputum daily later larger quantities of a greenish yellow purulent character appear Unless hemoptysis occurred just before the onset the sputum usually is not bloody Herpes labialis is rare The leukocytes of the blood usually range between 12 000 and 18 000 per cu mm seldom above 20 000 The polymorphonuclear neutrophils seldom exceed 80 per cent of the total and usually fall short of this Because of the type of onset and the signs of lobar or lobular consolidation the picture may resemble closely that of a pneumococcic infection (see Differential Diagnosis) Subsequently however the longer course, the bacteriologic findings and the excavating nature of the lesions prove the true nature of the disease The patient may die within four to twelve weeks but in some cases the course settles down to a subacute or chronic pace

More often the onset is attended by *grippe like symptoms* such as fever weakness fatigue and mild aching in the muscles which subside after a week or several weeks perhaps to recur at intervals when the patient again undertakes exertion In other cases and this is very common there is an insidious unexplained slow loss of weight increasing fatigue and impairment of staying powers under ordinary conditions of work or activity These symptoms continue for weeks or months before the patient is aware of serious difficulty, then he may find an afternoon fever of a fraction of a degree to several degrees which has probably been present longer than he realized The usual rest does not restore his energies he finds his efficiency impaired and he is puzzled by his inability to concentrate on his work Others are disturbed by some particular constitutional symptoms such as *sweating* at night *amenorrhea* or *anorexia* and *indigestion* Under any of these conditions it is learned usually that the patient previously has had some *cough* and *expectoration* or at least a clearing of the throat in the morning Sometimes he will report that there has been a little blood in the sputum at irregular intervals In other instances *hemoptysis* may be the initial symptom so far as the patient is subjectively aware and this may consist only of a few spots or streaks of blood in the sputum or free and profuse bleeding He may find a small amount of blood accumulated in his throat upon awakening in the morning *Pleurisy* may be the outstanding initial symptom The pulmonary lesions may have been quiescent and the secondary pleural invasion may produce an acute fibrinous or serofibrinous inflammation with characteristic onset of acute pain in the chest aggravated by breathing fever prostration and dyspnea if the fluid ac

cumulates rapidly Much less often the first symptoms are related to a perforation of the pleura and the development of acute *pneumothorax* pain in the chest may be sudden and tearing and the dyspnea so acute that the patient collapses Following this, tuberculous or mixed infection empyema may develop Other tuberculous lesions closely or remotely related to the pulmonary focus may cause initial symptoms Hoarseness, dryness and tickling in the throat or other symptoms of acute or chronic *laryngitis* may be the first to arrest attention Acute *perianal abscess* or *fistula in ano* likewise may dominate the picture and first impress the patient

A patient does not sense relationships between symptoms of various kinds, consequently those which he describes as initial often are found to be secondary and sometimes quite remote After he has learned the true nature of his disease and some of its peculiarities he may be able to recall from the past significant episodes which had been entirely forgotten (See also the descriptions of pulmonary manifestations under generalized Lymphohematogenous Forms of Tuberculosis)

Symptoms of Pulmonary Tuberculosis —*Fever* —The fever of tuberculosis one of the commonest manifestations of toxemia is usually well tolerated by the patient It is not unusual to find him with a temperature of 103° to 105° F stating that he feels well except perhaps for some associated flushing and sweating Some even feel exhilarated or buoyed up others are more disturbed and complain of the unpleasant warmth Usually the temperature is found normal or subnormal in the morning the rectal reading sometimes being as low as 96.5° or 97° F and there may be considerable prostration and weakness The normal point may be reached late in the morning or about midday, after which the temperature begins to ascend Between four and eight P M it reaches its height which in acute cases may be 105° or 106° F More commonly in subacute or mild cases it ranges up to two or three degrees above normal In most cases a low or moderate fever recurs each afternoon or evening for some days or weeks and in the advanced case this may continue for many months During grippelike episodes the temperature may rise to 103° or 104° F daily for a week or so then gradually subside by lysis until it is normal after several weeks In acute tuberculous pneumonia often in pleurisy with effusion and sometimes in the presence of other complications the fever is hectic and temperature swings from 97° or 98° F in the morning to 104° F or 106° F in the afternoon for some days and within a lower range for many weeks In advanced chronic cases there is sometimes a reversal of the temperature curve with a high rise in the early morning In the incipient stages or during the early reactivation of old lesions slight afternoon fever may occur upon unusual exertion but this quickly disappears with rest and the patient may be entirely unaware of it unless a routine recording is made

Chilliness is sometimes a complaint associated with fever of 103° to 105° F, especially if this appears suddenly but ordinarily the patient has no such experience In fact the absence of chills at the onset and afterward is sometimes a point of value in differential diagnosis Likewise the patient seldom develops herpes labialis and if this occurs it is explained usually by some intercurrent acute respiratory infection

Sweating is not a feature of early tuberculosis and is not often a symptom except in the febrile and exhausted states Then it occurs usually at the time of the temperature rise and immediately afterward In some cases in which there is extensive excavation of the lungs and secondary suppurative infection the sweats are drenching and prostrating

Malaise lassitude and *fatigue* are the most common symptoms of tuberculous toxemia At first they are noticed toward the end of the day s activity when the patient may eschew his usual diversions or interests in order to get additional rest If he is the type to disregard such mild symptoms he may become irritable grouchy and impatient However the symptoms are not always unpleasant and may be evidenced only as an urge to rest and sleep If the toxemia increases its effects become manifest earlier in the day and the patient may even notice that on awaking his vigor and energy are not restored In progressive disease the languor grows finally into a profound weak

ness and exhaustion Nevertheless there may be little of the discomfort restlessness and mental depression which frequently characterize toxemias of other kinds

Loss of weight and impairment of tissue tone is also common At the true onset there may be no loss and a few patients even report gaining when their disease is first discovered The loss is usually gradual at first and may amount to only four or five pounds during several months Young people may fail merely to gain at the expected rate During acute and febrile phases the nutrition suffers much more rapidly and pronouncedly During tuberculous pneumonia for instance thirty to fifty pounds may be lost by a formerly robust person in six or eight weeks The impairment is first at the expense of the fat but later there may be wasting of the skeletal muscles and some atrophy of the skin The parenchymatous organs are more resistant but may undergo degenerative changes in chronic advanced stages of the disease

Cardiocirculatory instability is also a usual symptom and may persist long after the temperature becomes normal The customary manifestation is tachycardia the cardiac rate is regular and accelerated to 80 or 90 per minute during the early phases later even more After exertion or excitement the quickened rate does not subside as soon as might be expected The pulse is soft and the systolic blood pressure may be low frequently 90 to 100 mm Hg The circulatory tone may be poor and the patient may complain of clamminess and coldness of the hands or feet the nails may be bluish Clubbing of the digits may never develop and only in advanced complicated cases is it occasionally extreme Malar flushing and other local thermic disturbances are related to fever and vagosympathetic reflexes Except for the lowering of tone and the accelerated rate the cardiac function usually continues normal throughout the patient s illness In advanced fibroid forms of pulmonary disease however the progressive reduction of the pulmonary capillary and alveolar bed gives rise to increasing dyspnea and cyanosis and imposes an increasing burden on the right heart which occasionally may dilate and fail (cor pulmonale)

Pallor and *secondary anemia* may be pronounced symptoms in the advanced stages particularly if there is associated intestinal tuberculosis or amyloidosis In the earlier stages however anemia is usually only slight

Digestive symptoms of a vague character are frequent due particularly to the toxemia Severe distress such as dysphagia is not observed unless there is extensive tuberculous involvement of the larynx or pharynx Anorexia, manifested as an indifference to food or a capriciousness of the appetite is frequent but usually corrects itself as the toxemia abates after which the patient even though confined to bed may eat heartily In protracted cases there may be a mild or moderate gastritis caused in part by the irritation of swallowed purulent discharges from the lungs The stomach is rarely involved by an actual tuberculous lesion Vomiting is unusual unless the patient has advanced disease of the lungs and a harassing cough In these cases the continued irritation and effort to raise the bronchial discharges especially in the mornings may induce nausea and vomiting and occasionally the patient may lose several meals during the day (emetic cough) Intestinal symptoms such as seizures of colicky pain and diarrhea alternating with constipation strongly suggest an ulcerative lesion in the bowel as a secondary complication

Menstruation may be delayed in a tuberculous girl and in older women may be irregular and scanty but as a rule this is observed *only after disease is well established* Amenorrhea is unusual except during the very febrile stages The *fertility* of tuberculous women is somewhat impaired and in the advanced stages of the disease spontaneous *abortion* is not uncommon A striking observation however is that chronically tuberculous women may bear a number of children There is little or no impairment of the sexual functions otherwise During the early and middle stages of the disease neither the *libido* nor *potentia coeundi* are appreciably reduced

Nervous and *psychic disturbances* are mild or entirely lacking In most of the early and moderately advanced and many of the far advanced cases there is no appreciable change and the patient s reactions are quite normal under the circumstances Later he

may become rather neurotic dependent introverted and depressed (Schultz) This mood, however, is usually surprisingly mild considering the discouragement which such a chronic illness often entails *Suicidal tendencies* or attempts are most uncommon Euphoria which once was considered to characterize tuberculosis is not often noticeable except during the late or terminal stages *Toxic psychoses* are very unusual

Dyspnea is not usually an early symptom Slightly or moderately accelerated respiration may be noticeable during the febrile periods or in more advanced fibroid cases in which there is a good deal of secondary emphysema Granulomatous or stenotic tuberculous lesions of the trachea or bronchi sometimes account for dyspnea Sudden or rapidly developing dyspnea is usually traceable to some complication such as ulceration of the pleura and pneumothorax or rapidly developing serous pleurisy

Cough is the most common local symptom and like others of this class, seldom develops until the pulmonary lesion has broken down and ulcerated into the bronchi In the earlier stages cough is most pronounced when the patient awakes in the morning and is due to irritation of the bronchial mucosa from the accumulated discharges Occasionally cough is attributed to a reflex from irritation of the pleura, and later it may be traced partly to tuberculous involvement of the larynx At first the symptom is usually slight and is quickly relieved after the small accumulation is cleared from the trachea and larynx Later especially if pulmonary excavation extends and the discharges increase the symptom may become very troublesome interfering with eating and sleeping Finally the patient may become exhausted from the persistent but ineffective attempts to clear the passages Tuberculosis of the larynx or of the trachea and bronchi in some cases becomes so severe that these symptoms predominate the cough may then be of a distressing stridulous and painful character

Expectoration—During the initial phases of the pulmonary infiltration there is seldom any expectoration except perhaps a little clear glary mucus Later however expectoration is a most common symptom Its quantity and frequency are variable Only a few particles of mucopus may be brought up in the morning by clearing the throat or a few coughs, gradually this may increase In other cases expectoration starts more *abruptly* and may soon amount to 1 ounce or so in a day In any case with progressive pulmonary excavation, the quantity usually increases until 2 or 3 ounces are produced each day, mainly in the morning In advanced cases 10 or 12 ounces may be brought up daily, particularly after secondary infection of cavities has occurred The sputum is not foul except in the unusual case in which secondary anaerobic infection develops in the bronchi or pulmonary cavities When expectoration is slight the flecks of pus are seen in the clear mucus In caseous pneumonic cases, particularly at the start of excavation the sputum is purulent and of a greenish yellow color but later this usually becomes yellow and the admixture of mucus is noted In more chronic cases the mucopus is of a coherent, sometimes tenacious character The sputum on standing retains its homogeneous mucopurulent character and does not separate into layers The quantity and the character of the expectoration reflect to some extent the changes occurring in the pulmonary lesions A daily production of 2 or 3 ounces of purulent green matter speaks for a caseous pneumonic liquefying lesion A change to yellowish more mucoid sputum suggests a subsidence of the ulcerative process indicated further by a diminution of the amount and a continuing decrease of the purulent element Sudden and marked variations in the quantity of the sputum may be due to bronchial occlusion or to the rupture into the lung of a localized fluid collection in the pleura

Hemoptysis—Blood spitting occurs in more than one half of all cases of pulmonary tuberculosis As a rule the quantity is small consisting of streaking spotting or pinkishness of the sputum in the mornings but copious bleeding is not rare Hemoptysis usually is due to the ulceration or weakening and rupture of the walls of the vessels in tuberculous cavities Infrequently in chronic healed cases it may be traced to the mechanical rupture of superficial vessels in the walls of distorted bronchi An ulcerative lesion in the trachea or bronchus also is an infrequent cause As a rule the symptom

is obviously not an indication of early disease Bleeding may start at any time during the day or night but has been observed more frequently in the early hours of the morning Exceptionally it is induced by a violent straining effort or by trauma Staining or streaking of the sputum may occur without other sequels but in other cases is a precursor of more copious hemoptyses Frank hemoptyses however appear most often without forewarning and the patient may be awakened with a salty taste in the mouth or in the course of his work may notice a warmth welling into his throat In a minority of cases there is a feeling of congestion in the chest for a few days before the bleeding Because of such an experience previously an occasional patient is able to predict the hemoptysis In women there may be a definite relationship with menstruation and a few have recurrent hemoptyses monthly During the bleeding the patient may notice boiling or bubbling sounds in his chest localized to one side or to the center The blood may be raised easily or may flow so freely as to cause severe choking coughing and gagging

Immediately fatal hemoptyses occur only in a small minority of the cases usually of long standing fibroid cavernous tuberculosis in which vascular granulation and connective tissue have proliferated in the cavity walls a vessel may undergo gradual aneurysmal dilatation (Rasmussen) until it finally gives way The patient s lungs are quickly inundated with blood in which he drowns within a few minutes Fatalities in cases in which the amount of blood lost does not seem to be an adequate explanation have been ascribed to spasm of the glottis or reflex stimulation of the respiratory center through the autonomic nervous system As a rule however a single hemoptysis amounts to only several ounces occasionally to 10 or 12 ounces The bleeding is then usually arrested by the deposition of a clot at the site of the vascular rupture Dark clots may be expectorated for several days sometimes in the form of bronchial casts This may be the end of it but there may be a few or many recurrences at intervals of hours days or longer periods Then the loss of blood may cause secondary anemia The patient may become nervous and frightened or may go into mild shock with fearfulness pallor coldness of the extremities tachycardia and weakness sometimes sweating Vomiting may occur soon after especially if the patient has swallowed much blood Within a day or two there may be a rise in temperature of several degrees usually traceable to the aspiration of blood into the lower lobes of the lungs The inflammatory reaction may be mild and fleeting but often continues if tubercle bacilli have been carried into previously healthy alveoli Such *posthemorrhagic tuberculous pneumonia* then may be acutely progressive and cause the patient's death within four to eight weeks Rarely the hemoptysis occurs at the moment of a pleural perforation and pneumothorax when most of the blood extravasated from the cavity may accumulate in the pleural space

Pain in the chest is usually a symptom of inflamed pleura It may be an early complaint therefore if the initial pulmonary infiltration is situated close beneath the pleura facilitating such secondary extension The pain may be slight dull and recurrent or acute sharp and stabbing and may be aggravated by respiratory effort Usually it is localized fairly closely over the site of the pleural irritation but may be referred to the hypochondrium and to the trapezius ridge in case the diaphragmatic pleura is involved Acute pain does not persist as a rule for more than a few days but hyperesthesia of the skin in the areas of intercostal nerve reference may continue a few days longer In cases associated with chronic adhesive pleurisy a dulness heaviness soreness and aching of the side is a very common complaint and is particularly noticeable during fatigue and during cold damp weather Such sensations may be noticeable for many years after all activity of the lesions has subsided and the patient is sometimes relieved by the assurance that these are healing pains Mild retrosternal distress is complained of by emphysematous patients who are dyspneic and by patients with acute pneumonic tuberculosis A sudden stabbing pain in one side or behind the sternum followed immediately by shortness of breath and other manifestations is usually indicative of collapse of the lung and acute pneumothorax

Wheezing and *stridulous breathing* is

occasionally a complaint in cases of cavernous tuberculosis, less often in others The wheezing may be noticeable behind the sternum but more often is localized to one side of the chest and is due usually to distortions or stenoses of the bronchus or trachea caused by tuberculous ulceration, granulomas or cicatrices Rarely the trachea becomes so filled with granulations that suffocative attacks may occur In old standing fibroid cases wheezing may be referable to catarrhal accumulations in distorted bronchial tubes

Hoarseness may be the result of temporary congestion of the larynx from incessant coughing Persistent hoarseness dryness and tickling of the throat are caused often by laryngeal tuberculosis

Symptoms of Extrapulmonary Lesions.—Since the majority of patients with advanced pulmonary tuberculosis in time develop one or more lesions in the larynx intestine or other parts of the respiratory or alimentary passages clinical manifestations may be referable in small or large part to such complications A febrile exacerbation may be due to the onset of serous pleurisy which may not assert itself at once in any other way Huskiness of the voice in the morning may be the first evidence of tuberculous laryngitis while the feeling of aural fulness without pain and the development of slight deafness may herald tuberculous otitis media Lagging of the appetite and failure to gain weight at the expected rate in a patient whose pulmonary lesion is doing well may be the first inkling of ulcerative intestinal tuberculosis while the complaint of a tender hemorrhoid may in fact turn out to be a tuberculous perianal abscess A sore spot on the tongue which fails to disappear in a few days may be a tuberculous ulcer Headache persisting for a few days or more may be the only forewarning of tuberculous meningitis

Physical and X Ray Examination in Pulmonary Tuberculosis.—The examination of a patient for pulmonary tuberculosis should be thorough and complete Signs discovered in the chest may be relatively slight and inconclusive and the finding of some secondary lesion may give the most important clue to the diagnosis Through the various channels of systemic infection associated lesions may originate at any time and may be easily overlooked if the examination is cursory and limited Similarly, the systemic effects of the toxemia must be sought for and evaluated before the diagnosis can be said to be complete The classical steps of the physical survey, *i e* inspection, palpation, percussion and auscultation should be carried out with the patient stripped so that all accessible information may be obtained The patient should be made to feel at ease and should be carefully instructed to cooperate fully, particularly during auscultation of the lungs Likewise x ray examination should be carried out with the approved technic Fluoroscopy is useful and sufficient to visualize changes in respiratory mechanics and gross densities in the lungs which may be due to tuberculous lesions However the greater accuracy of the roentgenogram must be appreciated, particularly in detecting early lesions

Physical Examination of the Patient with Limited or Early Pulmonary Tuberculosis—The lesion while small or only moderately advanced may be of an early exudative nature or longer standing and fibroid In the case of a relatively early lesion physical examination reveals no superficial abnormalities or perhaps only slight evidence of anemia and loss of weight The temperature may be found normal or elevated a fraction of a degree to several degrees and the pulse may be slow or moderately accelerated Careful examination of the chest may not reveal abnormal signs or one may detect definite changes such as slight dulness bronchovesicular breathing and a few persistent crepitant or moderately coarse rales Rales alone may be found in an area scarcely more than 1 or 2 cm in diameter The roentgenogram as a rule reveals evidence of the lesion more precisely as a soft cloudy mottling often associated with small honeycombed areas of rarefaction or larger round zones of similar translucency which represent cavities It must be repeated that the early infiltration which has not yet ulcerated frequently does not produce abnormal physical signs but the x ray almost always shows the characteristic shadows Very infrequently in the case of a small tuberculous lesion the roentgenogram is negative or indeterminate while definite rales may be heard in a given spot

Oblique roentgenographic views or other special views then may reveal the mottling or rarefaction which in the customary postero anterior view was concealed by the interposed density of the heart or some other structure These evidences of the lesions are usually disclosed in the upper third of one lung not infrequently beneath the level of the clavicle but sometimes exclusively above it Signs of similar or different intensity and variety may be detected sometimes in both lungs These may be located on one side in the upper third and at the apex of the opposite lung or there may be other variations such as apical signs on one side and basal signs in either one of the lower lobes In a few cases the signs are limited to the middle or lower part of the interscapular region on one side occasionally even below this level In some the original apical lesion is so slight as to give no definite signs either by physical or x ray examination while the obviously secondary lesions are easily detected

Long standing and *fibroid lesions* may betray their presence through the changes due to retraction and shrinkage of the fibrous tissue Thus a rather limited depression of the clavicular fossae on one side slight or moderate atrophy of the muscles in this region limitation of motion of the ribs and deflection of the trachea give the main clue to the long duration of the lesion Isolated nodular fibrotic or calcified lesions such as those of the primary complex usually are not detected by physical examination but cast characteristic dense sharply circumscribed shadows in the roentgenogram

Physical and X Ray Signs of Advanced Lesions in Pulmonary Tuberculosis—There is no limit to the variety of signs which may be produced by tuberculous lesions which have passed the early phases If the disease remains confined chiefly to one lung this may be converted into a fibrous shrunken mass with a variety of secondary effects such as flattening and immobilization of the hemithorax atrophy of the muscles and skin on this side inequality of the pupils from involvement of the sympathetic ganglia flushing of one cheek from a similar cause dilated superficial venules of the skin of the chest marked deflection of the trachea and retraction of the heart The roentgenogram may show a shrunken and opaque lung and the retractions associated with it while physical examination may reveal dulness to flatness bronchial and amphoric breathing post tussic suction widely distributed rales and many other classical signs In the case of advanced bilateral fibroid nodular tuberculosis secondary emphysema may be conspicuous and the physical signs of this together with few rales may leave one in doubt until the roentgenogram shows that typical distribution of nodular and streaky shadows throughout both lung fields

Extensive bronchopneumonic or pneumonic lesions which have not existed long enough to produce such secondary changes give rise most constantly to widely distributed rales which vary from the crepitant quality in the early stages of infiltration to moderately coarse bubbling and consonating rales after the lesions have caseated and undergone liquefaction and ulceration With these are discovered varying signs of solidification and excavation depending on the concentration of the lesions in a given lobe and their state of degeneration Physical signs then may be more informative than the roentgenogram since in the latter the opacity may be so complete that detailed structure can no longer be made out Smaller bronchopneumonic lesions however are usually depicted more faithfully by roentgenographic than by physical signs In all these situations the findings may be associated with or modified by changes in the pleura or other adjacent structures A large pleural effusion may obscure pulmonary lesions while more chronic pleural changes may be well revealed by peripheral densities and retractions which stand out in contrast with the air bearing lung

Complete examination of the body may bring to light changes outside the thorax also Thus the discovery of an inflammatory thickening of one vocal cord of a phlyctenule in the conjunctiva of a nodule in the epididymis or of a fistula in ano may be most important factors in constructing the complete picture of the disease

Tuberculin Tests—The tissues of the tuberculous patient with few exceptions react with inflammation upon contact with products of the tubercle bacillus such as

tuberculin Many methods of application have been used for diagnostic purposes, and tuberculin has been introduced into the eye, and upon, into, and beneath the skin The tests now employed most frequently are the cutaneous intracutaneous and percutaneous The *cutaneous test* (von Pirquet) is made by lightly scarifying the skin of the volar surface of the forearm and applying on this a drop of pure Old Tuberculin (O T) The *intracutaneous test* (Mantoux) is made by injecting 0 1 cc of a measured dilution of tuberculin into the superficial layers of the skin creating a wheal Old Tuberculin or the purified protein derivative (Seibert's P P D) may be used, in terms of Old Tuberculin the initial test dose in sick patients is not more than 0 01 mg while in apparently healthy subjects it is usually 0 1 mg By graduated steps allowing an interval of four or five days to elapse subsequent tests may be done with stronger doses (ten times the previous strength) in order to detect slight hypersensitiveness but the dose is usually not carried beyond 1 0 mg O T A reaction is indicated by induration of the cutaneous tissues which may be appreciated by palpation and an area of redness varying from one to several centimeters in diameter at the point of inoculation In severe reactions a vesicle may form and occasionally there may be slight necrosis of the tissues associated perhaps with the pink streaks of lymphangitis extending up the forearm and palpable slightly tender nodes in the axilla The *percutaneous* or *patch test* is performed by applying to the skin a strip of adhesive tape on which a piece of gauze saturated with dried tuberculin is attached The reaction is represented by a red papular and occasionally slightly vesicular eruption at the point of application The patch test is said to approximate in accuracy the Mantoux test using 0 1 mg O T it is not very dependable when applied to a very dry skin The local tuberculin reaction may be apparent within twenty four hours but the test is not considered negative until seventy two hours have elapsed In addition to the local reaction there may be a constitutional reaction indicated by malaise and fever, also a focal reaction may be demonstrated by increased inflammation about existing tuberculous lesions Constitutional and focal reactions particularly the latter are to be avoided since lesions may be aggravated in this way A reaction is interpreted as evidence that the patient has been infected and harbors a tuberculous lesion somewhere in his body However the test does not determine whether the lesion is active or healed and has no bearing on the clinical status or indications for treatment The reaction may be depressed or absent (1) if the dose of tuberculin is too small (2) if existing tuberculous lesions are thoroughly healed and calcified (3) in the presence of severe acute attacks of measles and influenza, (4) during the latter months of pregnancy (5) in some terminal cases of tuberculosis In some of these situations however, large doses of tuberculin may elicit a reaction If the patient is not very sick a negative test in the presence of gross lesions in the lungs or elsewhere is presumptive evidence that these are not tuberculous

Laboratory Findings in Pulmonary Tuberculosis—*Sputum*—Proper collection and examination of the sputum is most important There may be no sputum if the pulmonary lesion has not ulcerated Even after ulceration has occurred the quantity of discharge may be so small that the patient is not aware of it and unconsciously may swallow it In this case the patient is carefully instructed to collect in a suitable container any slight discharge collecting in the throat particularly in the mornings If he is unsuccessful in producing a specimen lavage of the fasting stomach in the morning using a clean technic may recover in the washings a few particles of pus which then should be stained and examined microscopically or the whole specimen may be centrifuged and concentrated before the examination Organisms may also be found in the feces

Ordinarily the patient with a pulmonary cavity will be able to collect mucopus upon awakening in the morning and this is the specimen needed Occasionally bloody specimens or the blood from a hemoptysis will be suitable for examination While a great many elements may be searched for such as elastic fibers various types of cells secondary organisms and albumin these have only subsidiary value unless some special point is to be determined The most impor

tant necessities are an estimate of the character of the sputum and an effort to detect tubercle bacilli in it The sputum should be measured by volume or weight for each twenty four hours The character is noted as to appearance consistency possible layering and odor

Tubercle bacilli are detected by selecting mucopurulent particles smearing and fixing these on a glass slide staining by the Ziehl Neelsen method or some modification of it decolorizing with acid counterstaining and discovering on microscopic examination organisms which have retained the original dye In a recent modification carbolauramine is substituted for carbolfuchsin as the acid fast stain the tubercle bacillus is then discerned by the fluorescence microscope Such acid fast bacilli from the sputum are with rare exceptions tubercle bacilli Since this examination is so important in diagnosis it must be remembered that if the organisms are scarce in the sputum or are greatly diluted by the quantity of the latter examination of the smear may be negative In such cases therefore 2 to 4 ounces of the sputum are collected during the space of a few days if necessary and concentrated by centrifugation after chemical digestion The sediment is then stained to determine the presence of acid fast organisms Even then if there are only a few tubercle bacilli they may escape notice and it may be necessary to investigate further by inoculation of the collected sediment into guinea pigs or upon suitable culture media Perfection of the latter has partly displaced guinea pig inoculation Many comparative studies have been made and Loesch and Petrik report that in cases of pulmonary tuberculosis tubercle bacilli were discovered by culture in 24 per cent of the sputum specimens which were found negative on routine microscopic examination of a single smear or of the sediment collected after concentration With such exhaustive methods more than 90 per cent of all patients with active disease are found to show tubercle bacilli in the sputum and practically 100 per cent of those with pulmonary cavities *

Blood —In the early stages of pulmonary tuberculosis the erythrocytes and hemoglobin of the blood may remain unchanged later there may be evidence of secondary hypochromic anemia Similarly the leukocytes may not be changed in the early stages As activity continues and lesions progress the total leukocyte count may increase This may amount to 7000 or 8000 per cubic millimeter in the moderately active case and in acute tuberculous pneumonia may rise to 15 000 or more it is most exceptional however to observe a count as high as 20 000 Associated with the rise in the total count an increase of polymorphonuclear neutrophils and of monocytes may be noted together with a relative decrease of lymphocytes The Schilling count may reveal a shift to the left Later as the disease regresses and heals the cytologic picture may return to normal These changes parallel those of the pulmonary lesions fairly closely but there are certain discrepancies to be noted Thus during the early progression of the pulmonary lesion there may be no change detected in the leukocytic picture In fibroid cases the white cell count may deviate slightly or moderately from normal even though the patient is able to undertake a certain amount of activity with safety Various cytologic formulas have been suggested for estimating the trend and prognosis of tuberculosis These may be of value especially when set down in series during intervals of time The Medlar index (neutrophil–lymphocyte ratio with assigned values for abnormalities in monocytic percentages and in total leukocyte counts) is preferred by some Boissevain however finds the total neutrophile count is ample as an index

The *sedimentation rate* of the erythrocytes is accelerated in practically all phases of progressive febrile tuberculosis varying from a slight degree in the mildy progressive cases to a very marked one in highly febrile stages The sedimentation rate has no specific value diagnostically but is particularly useful in helping to determine the activity of the lesions Its reliability in this respect must be accepted with certain qualifications since the rate may be entirely within normal limits during the initial phases of the early pulmonary lesion in more advanced progressive cases when the patient is kept

* The techniques of sputum examination are described in a booklet "Diagnostic Standards" which may be obtained from the National Tuberculosis Association 1790 Broadway New York City

quietly at rest in bed and in old fibroid cases even though a pulmonary cavity may still be present

The *tuberculosis complement fixation test* is positive in most cases of pulmonary tuberculosis but also in many persons who have healed lesions and have never suffered from the disease in a clinical sense The test has not been found of great value in following the course of the disease Many other serologic tests have been devised, most of them of a nonspecific nature which show variations according to the activity of the tuberculous lesions However they are secondary in importance to accurate information of the clinical behavior the roentgenographic changes, and the character and content of the sputum Similarly in advanced cases disturbances in the balance of the mineral salts of blood of certain enzymes such as lipase and of vitamins may be demonstrated These changes are nonspecific are not of diagnostic help and as a rule do not yield many suggestions for treatment Recently, by means of electrophoresis Seibert and Nelson have found abnormal values for the serum proteins which seem to parallel the clinical course of human tuberculosis The conspicuous changes were a decrease in albumin, a rise in the gamma and alpha globulins and the appearance of an unknown (x) component

Urine—In febrile tuberculosis the urine commonly shows slight traces of albumin Protein loss through the kidney may become marked after amyloid changes have occurred From the results of animal experimentation it has been suggested by some that tubercle bacilli free in the blood stream may be excreted through the intact and normal kidney and then may be discovered in the urine (excretory bacilluria) In human beings however experience indicates that this must be a rare happening and the discovery of bacilluria is taken as presumptive evidence of a tuberculous lesion in the urinary tract or in the genital organs The discovery of pus cells and an abnormal number of erythrocytes or persistent albuminuria in a patient with pulmonary tuberculosis should always lead to a further investigation for the presence of a renal lesion

Pleural Fluid—In some cases of pulmonary tuberculosis complicated by a pleural effusion the discovery of tubercle bacilli in the aspirated fluid may verify the diagnosis when this evidence is lacking on account of negative tests of the sputum

Basal Metabolic Rate—In afebrile cases of pulmonary tuberculosis this is found to be normal unless there is some independent cause for variation In febrile cases the rate is elevated according to the degree of fever

Respiratory Function—In the presence of limited lesions the respiratory function is not materially disturbed Later it may be impaired because of the extent of the involvement, the shrinkage of fibrous tissue and the associated distortion of blood vessels Such an effect may be aggravated also by pleural adhesions and by retractions of the heart or constrictions in the pericardium The nature and extent of the changes may be estimated by functional tests designed to measure pulmonary ventilation diffusion and circulation

Diagnosis of Pulmonary Tuberculosis—Tuberculosis should be considered as a possible cause (*a*) in any patient who presents vague symptoms of loss of weight malaise and easy fatigue particularly when this is associated with persistent cough (*b*) in any patient particularly a young person who has recurrent or prolonged attacks simulating grippe or influenza (*c*) in any patient who has atypical or unresolved pneumonia (*d*) in any patient who has cough and expectoration persisting for more than several weeks even though there may be little or no impairment of the general condition (*e*) in any patient who spits blood (*f*) in any patient who has pleurisy, especially with effusion (*g*) in any patient with a persistent unexplained fever (*h*) in any patient with other mild or obscure lesions such as persistent lymphadenopathy fistula in ano and chronic laryngitis giving rise to chronic hoarseness The diagnosis then depends particularly upon physical x ray and laboratory examinations Under such circumstances the finding of a lesion usually in the upper one half of the lung which gives the characteristic x ray appearance of an infiltration or fibrosis with or without cavity and with or without demonstrable physical signs such as rales warrants the presumptive diagnosis of tuberculosis If there is no demonstrable cavity and no sputum the

Fig 29—Infiltration of mixed exudative and productive character in the upper third of the right lung

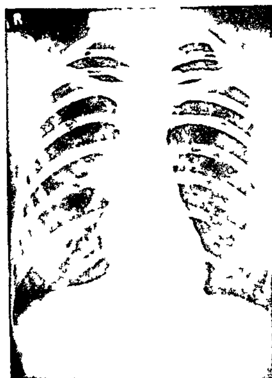

Fig 30—Early infiltrate in the lower lobe of the right lung at the level of the seventh rib posteriorly Tuberculosis of the right bronchopulmonary lymph nodes

diagnosis is confirmed by a period of observation during which the lesion persists or gradually changes If excavation is demonstrated or suggested by the other examinations the diagnosis may be verified by the finding of tubercle bacilli in the sputum The failure to find bacilli in a case in which there is moderate or fairly copious mucopurulent sputum weighs heavily against the diagnosis of tuberculosis The finding of tubercle bacilli in the discharges or material secured from other lesions such as pleural effusion

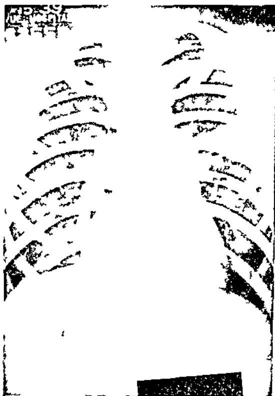

Fig 31—Tuberculous cavity in th right lower lobe at the level of the eighth rib posteriorly Exudative infiltrate in the middle of the left lung representing a bronchogenic extension from the cavity

or pus from a tuberculous fistula strongly suggests that the pulmonary lesions are also tuberculous The finding of rales in the upper one third of the chest in a case in which the roentgenogram shows no parenchymal change and in which the sputum test is negative leaves the diagnosis in doubt and raises the question whether the lesion is nontuberculous The finding of physical and x ray signs exclusively in the lower one half of the chest does not rule out tuberculosis as a cause but if in addition there

is mucopurulent sputum devoid of tubercle bacilli tuberculosis as a rule can be excluded

Modern methods of *tuberculosis case finding* among apparently healthy people afford another approach These surveys are usually conducted by routine x ray examination of the chest, with or without a preliminary tuberculin test In about 2 per cent of apparently healthy people densities are discovered in the lungs which may be tuberculous The lesions are usually in the upper one half of the chest often confined to one lung and may be of a caseous or fibrous character Discovery of such a shadow in the roentgenogram necessitates a complete history of the case complete physical examination, and study of the sputum These tests together with the necessary period of observation usually confirm the tuberculous nature of these lesions

Differential Diagnosis of Pulmonary Tuberculosis—The approach to differential diagnosis varies according to the presenting findings Thorough and careful study of the case usually enables one to arrive at a definite conclusion

In a patient who develops unexplained fever and who is discovered to have an exudative infiltrative lesion of the lung which has not ulcerated distinction often has to be made between early tuberculosis and *simple bronchopneumonia* especially if the lesion is confined to an upper lobe Demonstrably rapid changes in the lesions within a few days or a week and failure to find tubercle bacilli usually identify bronchopneumonia as such, while the failure of the lesion to clear in the expected time favors tuberculosis Occasionally acute caseous pneumonia occupying a large part of the lobe or lung may be confused with *pneumococcic lobar pneumonia* and the confusion may be increased by the finding of pneumococci of a higher type in the sputum While in a rare case of tuberculous pneumonia the leukocytes of the blood may rise to 20 000 the count seldom attains the height commonly seen in lobar pneumonia nor is there often such a pronounced relative increase of the polymorphonuclear neutrophils Since caseous pneumonia usually represents an acute confluent bronchopneumonic extension from a tuberculous cavity tubercle bacilli will be found on careful search of the sputum which, as a rule is not rusty although it may be bloody In caseous pneumonia the signs of cavity may be detected on physical and x ray examinations If not immediately the diagnosis usually can be made in the space of a relatively few days Acute bronchopneumonia due to organisms such as *streptococcus* or *anaerobic bacteria* which commonly goes on to abscess formation may be confusing because of the pattern of the pulmonary lesions simulating tuberculosis The acute onset often with chills the leukocytosis the finding of an abscess or cavity and the failure to demonstrate tubercle bacilli in the sputum are presumptive evidence against the tuberculous nature of the disease while a great predominance of other specific organisms may give the real clue One must be certain, however that common pyogenic organisms are not merely contaminants from the mouth

Foulness of the sputum shortly after the acute onset of the disease always speaks for *putrid lung abscess* In long standing cases of chronic lung abscess a cavity or fibrotic lesion may be discovered in the upper part of one lung and this may give rise to suggestive symptoms such as hemoptysis The history of onset particularly the history of fetid expectoration and the failure to demonstrate tubercle bacilli usually indicate the diagnosis

When tuberculosis is suspected as the cause of a *protracted and obscure fever* the failure to find a pulmonary lesion is presumptive evidence against this diagnosis but it may be necessary still to rule out tuberculosis of other organs The same is true in any chronic debilitated state in which tuberculosis may be suspected

Bronchiectasis not infrequently must be differentiated in patients who give a history of chronic cough possibly with bloody sputum The lesion is usually in the lower lobes but occasionally is apical Rales may be heard but the roentgenogram fails to show the typical tuberculous infiltration and excavation and instead there may only be strandlike densities suggesting interstitial or peribronchial fibrosis This and the absence of tubercle bacilli from the sputum suggest bronchiectasis which may be verified by the use of bronchography with iodized oil

Cancer of the lung simulates tuberculosis because of the chronic cough, expectoration of pus and blood febrile episodes and gradual wasting Physical and x ray findings are more likely to be those of an invasive growth or of suppurative pneumonia secondary to the bronchial occlusion The failure to find tubercle bacilli in the purulent sputum is most important Bronchoscopy the biopsy of a superficial metastatic lesion in a lymph node or the finding of other internal metastases may be diagnostic

Pulmonary fibrosis and *emphysema* may have to be differentiated because of symptoms and because tuberculosis particularly the chronic hematogenous form sometimes is a cause Chronic cough occasional blood spitting and increasing weakness may be particularly suggestive In tuberculosis the fibrous changes are usually associated with calcifications identified by x ray Extrapulmonary lesions may also be found especially in the lymphatic system or in the abdomen The history of some other possible cause such as chronic paranasal sinusitis or exposure to injurious dust may give the proper clue In silicosis the nodular noncalcareous roentgenographic appearance of the lesions evenly distributed in both lungs particularly in the central portions is characteristic Association of the tuberculosis with silicosis a not infrequent finding may be suspected when there are confluent roentgenographic shadows in addition to nodular ones

Mycoses may produce changes simulating tuberculosis but these are unusual The lesions may be of a subacute bronchopneumonic or chronic granulomatous and fibrous nature and the pattern in the roentgenogram may simulate tuberculosis closely even to cavity formation In a patient suffering with a chronic cough expectoration and general ill health failure to demonstrate tubercle bacilli and the finding of specific fungi in the sputum by microscopic or cultural examinations may settle the diagnosis other tests used include the serum antibody titer skin sensitivity tests and virulence of the organisms for animals It is important to know whether there has been an opportunity for infection with fungi and whether there have been systemic lesions Fungi may be found in the sputum as contaminants from the mouth but these are usually scarce and nonpathogenic

Pulmonary lesions secondary to cardiac disease sometimes create a confusing picture The hemoptysis of mitral stenosis may be misleading at first because of the finding of rales and roentgenographic changes suggesting fibrosis and infiltration of the parenchyma Demonstration of the cardiac lesion the failure to demonstrate a cavity the lack of sputum containing tubercle bacilli and the distribution character and behavior of the lesions lead correctly to the conclusion that these are due to secondary fibrosis from congestion and stasis to infarction or to edema A pleural effusion clouding the picture may be found related to the same cause Rarely a pulmonary *infarct* may become secondarily infected and break down to form an abscess simulating a tuberculous cavity

Suppurative lesions in other structures which may become connected with the lungs must be distinguished Thus chronic pleural empyema which has ruptured into the lung may cause many symptoms common to pulmonary tuberculosis and the same may be said of chronic hepatic or subphrenic abscess which has perforated through the diaphragm into the lung A searching history of previous illnesses and operations and failure to demonstrate tubercle bacilli in the sputum usually eliminate tuberculosis

Unusual conditions such as Hodgkin s lymphoblastoma invading the lung from the mediastinum esophagotracheal fistula dermoid or parasitic cysts which have ruptured into the lung and aortic aneurysm producing bronchial stenosis by pressure may necessitate ruling out tuberculosis because of the symptoms of chronic pulmonary disease The clinical history the failure to find tubercle bacilli and the demonstration of other lesions especially in the mediastinum exclude tuberculosis as a rule and suggest the proper diagnosis

Prognosis of Pulmonary Tuberculosis —Because of the many factors which influence the course of the disease the prognosis is difficult Important factors which should always be taken into consideration include the extent and character of the lesions the clinical symptoms the age sex and color of the patient the presence of complications

and certain environmental conditions There is a definite correlation between the *extent of the lesions* and the ultimate prognosis Early or limited lesions without cavity formation almost always do well under suitable treatment in such cases the life expectancy, as indicated by studies such as those conducted by Trudeau Sanatorium is equal almost to that of groups of similar age in the general population The more extensive the pulmonary lesions the greater is the future hazard Patients with far advanced cavitary disease do not survive as a rule, more than two to five years unless some special treatment changes the course About one third of the patients with moderately advanced disease are reported dead within five years The *character of the lesion* is of great and sometimes paramount importance Lesions of a productive nodular character tend to run an indolent course and are more readily controlled by treatment the tendency to excavation is less, while delimitation by fibrosis is customary Exudative bronchopneumonic lesions may be resolved rather rapidly but there is almost always an unresolved caseous center and the predominating trend is for this to liquefy and slough into the bronchial tree with secondary extensions into the healthy parenchyma The instability of these lesions is striking particularly during the first year or two after their discovery The *size and character of cavities* also has a prognostic bearing particularly since these are sources of infectious discharge which frequently is responsible for secondary lesions in the lungs larynx and intestine there is also a liability to hemorrhage Patients with cavities more than 2 cm in diameter which are not suitable for treatment by collapse therapy usually remain more or less disabled and most of them die within five years However a patient with a small fibroid cavity may survive for many years despite tubercle bacilli being constantly present in the sputum On the contrary a cavity recently developed in a caseous pneumonic lesion impairs the prognosis greatly because of the likelihood of rapid dissemination The *distribution or concentration of lesions* is significant A moderate number of small lesions scattered in isolated positions throughout the lung usually offers a better prognosis than if these were concentrated in one area where the likelihood of excavation would be great

Clinical symptoms measure in an approximate degree the patient s reaction to the infection Thus, a young girl who reacts with prolonged fever usually does badly while an older person with more tuberculosis but no fever may have a better prognosis Another guide is the amount and character of the *sputum* a patient who has only a small quantity, mucopurulent and coherent may live for years without extension of the disease On the contrary, a large amount of more liquid sputum favors early extension In either case the number of tubercle bacilli in a given quantity of sputum may be approximately the same Generally however the prognosis is better if tubercle bacilli are scarce, since this may be interpreted as evidence that the cavity walls are relatively clean and not undergoing active necrosis *Complications* may alter or actually determine the prognosis A patient with a small cavity and good prognosis may be changed within a few days following a hemorrhage into one with desperate acute tuberculous bronchopneumonia The same may be true when ulceration of the pleura pneumothorax and mixed infection empyema rapidly develop Other complications such as tuberculous laryngitis or tuberculous enteritis impair the prognosis somewhat but, unless these in themselves are severe and extensive they may heal with the pulmonary lesions Nontuberculous complications similarly may have an important influence Severe diabetes mellitus especially when this is difficult to control renders the outlook less favorable Acute pulmonary complications such as putrid abscess may cause rapid extension of the disease People with arteriosclerosis usually do not have good resistance Active syphilis tends to impair the prognosis

The *age* of the patient is of great prognostic significance Tuberculosis acquired during infancy or early childhood is of serious portent as indicated by the careful studies of Wallgren Miriam Brailey and Edith M Lincoln Adolescence is a serious time with relation to pulmonary disease Young tuberculous girls have notoriously unstable lesions and the mortality is relatively high there is a similar trend some

what less striking among young boys Women past thirty have a relatively good prognosis while men in the older age groups have a higher mortality *Constitutional and racial characteristics* may be given some weight Under equal conditions Negroes do not survive tuberculosis as well as most whites Patients of poor constitutional make-up seem to react poorly although exceptions are numerous particularly when proper environment is provided

Controllable factors which have the most definite relation to prognosis are *early diagnosis and prompt and proper treatment* If the lesion is detected as an early infiltration which has not yet excavated and treatment is instituted without delay the prospect is that at any age and in almost any type of patient recovery will occur and a sufficient prolongation of treatment will avoid relapse

Treatment of Pulmonary Tuberculosis—Until recent years tuberculosis was seldom diagnosed until the patient developed symptoms clearly indicating treatment The perfection of diagnostic methods particularly the use of the x ray and the development of modern case finding surveys has altered and complicated the situation considerably Therefore the first task of the physician after discovering a tuberculous lesion is to determine its clinical status and whether treatment is needed Whatever the diagnostic approach may have been the patients generally may be grouped into (1) those who obviously require treatment (2) those who obviously do not require treatment and (3) those who are of uncertain status and may be observed for a time to determine the need of treatment The third group includes patients who may be observed (*a*) while they continue their usual activities and (*b*) those whose status is so uncertain that observation should be carried out under the conditions of bed rest

Those Needing Treatment—The first group comprises all patients with clinical symptoms such as fever malaise fatigue cough and expectoration and the spitting of blood It includes also patients with recently developed lesions or lesions the instability of which is proved or inferred it is to be emphasized particularly that these still may be in the subclinical phase producing few or no symptoms One of the commonest errors in practice is the postponement of treatment or minimization of its need until clear-cut symptoms have developed meaning usually that the physician fails to appreciate the significance of an early infiltrate until this has broken down into a cavity under his very eyes Also proper measures should be instituted promptly for the patient whose disease previously became arrested under treatment and who now shows indications of relapse such as the appearance of a positive sputum x ray evidence of a change in the lesions or undue constitutional symptoms such as great loss of weight

Those Not Needing Treatment.—The second group includes patients in whom the roentgenogram reveals the calcified residues of the primary complex which may have been acquired in childhood and has long since healed The important exception is the finding of large and multiple apparently calcified lesions often lymphatic in the chests of children or adolescent youths in these cases the occurrence of pulmonary tuberculosis later is considerably greater than it is in the general group of young people who react to the tuberculin test but do not harbor such large foci usually these are only partly calcified partly caseous often bacilliferous Healthy adults found to have obviously fibrotic scars at the pulmonary apices do not require treatment The same is true of adults who show the scars of old pleurisy or healed extrapulmonary lesions Periodic examination yearly is indicated because apparently healed tuberculous lesions frequently contain tubercle bacilli which may be responsible for extensions or relapses under the vicissitudes of ordinary living

Those Requiring Observation—Group 3*a* includes adults who have lesions of uncertain stability or apparently well healed lesions involving more than the pulmonary apices and who have vague symptoms of fatigue loss of weight or malaise In such patients particularly if they are more than thirty years of age these lesions usually do not change rapidly and observation may show that the symptoms are referable to some other cause As a rule it is best for the patient to continue working provided he follows a prescribed daily routine in order that his health may be evaluated accurately

The temperature and pulse should be recorded in the late afternoon and evening during the period of observation and all symptoms, even slight should be reported, specimens of sputum should be submitted for examination, even if the bronchial discharge is very scanty The leukocyte count and the erythrocyte sedimentation rate are particularly valuable supplements when estimated at intervals of one to several weeks, to show slight grades of toxemia and any change in the trend Roentgenograms of the chest should be made at least once every month Usually it may be decided within several months whether there is any instability of the disease necessitating treatment or whether the patient may continue at work under supervision at intervals of several months

Group 3*b* includes, mainly, patients less than twenty five years of age with lesions of doubtful status and those more than this age in whom competent fibrosis of the lesions is not readily demonstrable Any adolescent youth or any adult in his early twenties showing a limited pulmonary lesion which in the roentgenogram casts a soft poorly circumscribed shadow, should be observed under conditions of bed rest since such lesions are usually of recent origin unstable and potentially dangerous The absence of symptoms is no criterion that treatment is not needed Somewhat greater latitude may be allowed the older patient the roentgenographic appearance is the best means of deciding whether fibrosis is sufficient or whether the patient had better be in bed pending determination of this point During the period of observation definite symptoms may assert themselves though this is unusual, and reliance must be placed mainly on serial roentgenographic examinations In adolescent youths roentgenograms should be made for comparison at intervals of at least two weeks sooner if there are definite or doubtful symptoms in older persons the interval may be two to four weeks In either case after a period of stability is proved the examination should be repeated monthly and this is continued until the status of the patient is clearly determined Instability of the lesion whether progressive or regressive is an indication for treatment and the younger the patient the more strict this should be Likewise, searching microscopic and cultural examinations of the sputum and gastric washings should be made for tubercle bacilli, the presence of which indicates the need of treatment But—let it be stressed—negative findings do not mean necessarily that the lesion is not dangerous and not in need of treatment

Principles of Treatment—Since there is no known specific cure for tuberculosis treatment rests entirely on a recognition of the factors contributing to the resistance of the patient and the adjustment of the daily routine so that these may operate most effectively Many of the factors can be only suspected or indirectly identified experience, however, has proved their dependability as a basis of treatment The chief principle is *rest* which may vary from strict rest in bed to a combination of rest periods and regulated exercise The effect of rest is both local and general Diminution of the respiratory rate and amplitude implies lessened motion of the lung which is known to favor healing of tuberculous lesions Another effect which may be even more important than this is the diminution of the circulatory rate and of the volume of blood passing through the lungs A result of these mechanisms is lessened circulatory interchange between the lesion and the lymph and blood streams and diminished diffusion of toxins, manifested by the subsidence of symptoms such as fever and tachycardia The same mechanisms explain the observation that patients placed at rest often experience a prompt diminution in the expectoration and consequently of the cough while the sputum changes from a greenish purulent to a more mucoid yellowish consistency Rest also relieves certain local strains which at times may precipitate serious accidents such as hemorrhage or rupture of a weakened pleura Similarly the quieting of respiratory movements helps to avoid the inhalation into healthy parts of the lung of purulent discharges issuing from tuberculous cavities

Clinical experiences suggest that resistance is promoted by good physiologic tone of the alimentary and cardiocirculatory functions and by other less obvious vegetative responses Alterations of vascular tone and capillary permeability seem clearly to account for certain clinical phenomena such

as hemoptysis during menstruation and perhaps the exudative nature of lesions developing in the presence of uncontrolled diabetes Well maintained vascular tone may be assumed therefore to be a feature of good resistance helping to avoid harmful inflammatory reactions about old tuberculous lesions and to hold in abeyance such tendencies in recent lesions until fibrous encapsulation has had time to develop Bodily rest particularly if this is understood as complete physical relaxation and mental quiet undoubtedly contributes to the physiologic tone which always is an important and often the most important factor in recovery To think of rest only in its mechanical relation to respiratory motion is to take too narrow a view of the principles of successful treatment

While the immediate necessities of the case must be recognized and met treatment to be successful ultimately also requires planning according to a visualization of the future potentialities of the disease in each case this ability is acquired only by sound experience Potentialities may be quite remote and failure to comprehend them may not betray itself immediately but to the detriment of the patient only after a lapse of months or years To recognize and observe this principle therefore is one of the most responsible functions of the physician In a pulmonary cavity he visualizes the possible source of a pulmonary hemorrhage In a recently disseminated tuberculous bronchopneumonia he sees the potentiality of early resolution or early caseation and excavation In an early infiltration he senses the alternative of relatively rapid resolution of the peripheral exudate and subsequent fibrous encapsulation of the caseous residue or liquefaction and sloughing of the latter to mark the first of successive steps toward advanced bronchogenic tuberculosis He appreciates further that a long period of treatment to assure complete and durable encapsulation of the remains of the early infiltration is far superior in its ultimate results to the compromise of permitting the patient to return to work as soon as symptoms subside and then after relapse and cavity formation collapsing the lung by artificial pneumothorax As stated early diagnosis is the best guarantee of a good prognosis but the vital bridge between diagnosis and lasting recovery is the quality of treatment

Under rest treatment with the proper kind of clinical observation the limitations of the patient s resistance may be determined and special procedures may be adopted when needed Excepting unusually pressing situations time for this determination should be allowed It is not generally a good principle to proceed immediately upon making the diagnosis to some form of collapse therapy on the theory that mechanical pulmonary factors are the sole agencies in healing

Guides and Checks in Treatment—In order to apply the principles of treatment most effectively the observation of the patient should be systematic As a rule relatively simple clinical data supplemented by periodic examination of the sputum roentgenography of the chest and study of the blood suffice The temperature is recorded during the day at least every four hours occasionally two hourly observations may be desirable for short periods and it may be necessary sometimes to obtain nocturnal records also Unless there is some valid objection rectal temperatures should be taken since they are more dependable The pulse rate is recorded each time the temperature is taken it is well to remember that the pulse may continue unstable after the temperature remains normal and therefore may be considered a more sensitive indicator of toxemia or other disturbances The body weight is recorded every two weeks unless the patient is too sick Note is made of the patient s appearance his general feeling and of his vegetative functions A tendency to sweating coldness of the extremities irritability and digestive disturbances may be significant Likewise attention is paid to special symptoms such as pain in the chest hoarseness or diarrhea These may be indicators of some underlying change which can be determined by the proper examination

The sputum is collected during each twenty four hours in a disposable container so that the amount and character may be estimated If tubercle bacilli are found at the outset later examinations at intervals of a month may show some change such

as a diminution in the bacillary output, which with a diminution in the quantity of expectoration may be significant If bacilli are not found at the start such repeated examinations are indicated to verify the diagnosis and to detect early this evidence of an ulcerative process in the lung At the start the sedimentation rate of the erythrocytes and a complete total and differential count of the leukocytes should be recorded The milder the symptoms and the closer the approach to quiescence and arrest of the disease, the more likely are these estimations to be valuable Then a series of observations at intervals of several weeks or months may help to determine the trend of the disease and particularly the degree of stability attained under treatment

While repeated physical examination is indispensable its value is variable and it is not to be relied upon to detect early and slight changes in pulmonary lesions For this purpose the roentgenogram is much more dependable How often this examination should be made depends on the behavior of the case In young people with exudative and unstable lesions roentgenograms at intervals of a week show not infrequently definite extensions or regressions which are most important to recognize in old fibroid cases, few or no changes may be shown during long periods The interval must be determined therefore according to one s judgment of the potentialities at the start of treatment and for six months afterward this examination should be made at least once a month At any time an unexplained occurrence such as fever severe pain or breathlessness necessitates prompt investigation by physical examination and roentgenography or fluoroscopy The latter may be the most convenient and rapid way of determining certain changes such as pneumothorax

Application of Treatment—Treatment is carefully planned according to the existing and potential needs of the patient taking into consideration the personal social economic and environmental situations Modifications from a standard method are often indicated thus a patient discovered with advanced bilateral tuberculosis may be judged to have very little prospect of recovery and he may be left relatively undisturbed in his home since the important consideration is his personal comfort and contentment On the contrary, the benefits of treatment to be expected in an early case in a young person are so great as to justify radical dislocation of the domestic routine and heavy sacrifices by the patient and his family

The *place of treatment* is usually the first consideration While in hopelessly advanced cases the patient s comfort may be favored by his remaining in the home the possible hazard of infecting others in the household, particularly young children should be carefully investigated before sanctioning this Similarly it should be determined whether the responsibilities of the care of a chronic invalid may not impose excessive burdens on other members of the family possibly endangering their future health or security Under such circumstances it may be wise to provide for the patient in a sanatorium or nursing home A patient with moderately advanced or advanced cavitary disease particularly if there are serious symptoms such as hemoptysis or complications requiring investigation should not remain at home but is best treated in a nearby hospital If this is not accessible readily it may be necessary to tide him through the acute episode until it is safe to transport him to a sanatorium At the start young people with relatively early pulmonary tuberculosis usually require strict rest in the hospital or sanatorium where they may receive the education and instruction so vital to their complete and lasting recovery They profit by seeing patients with more advanced disease and are impressed with the wisdom of following medical advice in order to avoid this misfortune In the home the lack of companions who have similar objectives makes it more difficult for young people to take the cure Older seasoned patients who previously have undergone sanatorium treatment and now have relapsed sometimes do better at home where another adult is able to provide the necessary nursing and dietary care

CLIMATE may have a virtue as a part of the treatment but this depends on the individual situation Climate alone is of little value and its overestimation in times past deprived many a patient of his chance of recovery Other conditions being met a young person with recently developed and

not too advanced tuberculosis usually does well in a cool invigorating climate and he tolerates cold dry winters extremely well His physiologic tone seems to be promoted Old poorly nourished patients do best in a mild balmy climate High altitudes have a doubtful value except for the purity coolness and stimulating quality of the moving air they are contraindicated for the dyspneic patient with fibroid tuberculosis and emphysema Warm dry climates and a moderate altitude such as in southern Arizona are conducive to relaxation and rest during the winter for many patients with moderately advanced and chronic disease Whatever the merits of a given climate may be they may be far outweighed by economic or social considerations An indigent patient is best treated in a public hospital near his home and a patient with limited means usually responds best in a nearby locale where the expense is not great and he may be visited by his family at intervals Since the establishment of hospitals in many cities of the United States and other countries ample proof has been provided that skilled treatment in such well conducted institutions is the important element in recovery so much the better if these institutions are situated in the suburbs where there is at least a simulation of the quiet countryside

INSTITUTION OF TREATMENT —The *time for treatment* to be instituted is usually at once This is never disputed in the case with severe or alarming symptoms Postponement for a short time may be permitted in the adult patient with chronic tuberculosis obviously of long standing when this concession is necessary to permit settling affairs in business or at home The necessity of prompt treatment of the disease in adolescent youths or young adults however is too frequently underestimated Here the delay of a few days or several weeks may spell the difference between uninterrupted healing and early excavation and extension of the lesions The physician needs strong convictions and persuasive powers in this situation since the patient usually is unconvinced because of the lack of symptoms There are few circumstances in which the physician is more justified in taking an uncompromising stand to induce the patient and his family to take advantage of this rare chance for lasting and complete cure He is justified further in describing vividly the probable alternative

SCHEME OF TREATMENT —This is best illustrated by considering the patient with moderately advanced febrile tuberculosis As a rule it is best for him to understand from the outset that treatment will be long and recovery slow since such proper advice may permit him to arrange his affairs wisely and deter him from expending his financial resources rapidly with the hope of getting a quick cure Explaining in a simple way the mechanism and rate of healing of lesions is more likely to win the cooperation and acquiescence of the patient and his family than rash promises which later lead to disappointment and loss of confidence in the physician The patient must know the nature of his disease and the sooner he accepts the diagnosis and adjusts to it the more successful is his treatment likely to be The behavior of symptoms is also explained so that while he may be watchful he will not become unduly apprehensive as these fluctuate from time to time If he is able to cultivate and preserve a calm patient and cheerful attitude his progress is unquestionably favored this of course is a large task for the young active enthusiastic and emotionally high strung person but youth is more adaptable than sclerotic senescence

The *plan of treatment* is adjusted to individual indications The patient with obviously hopeless disease is not required to conform to the same stringent routine as the one in whom recovery is anticipated Elderly people with long standing fibroid tuberculosis often tolerate mild physical exercise well and may even be helped by this they are not advised to remain in bed constantly unless there is some special symptom requiring it With such occasional exceptions all patients with active or potentially active tuberculosis who have a prospect of recovery are kept strictly in bed Mildness or complete absence of symptoms is not necessarily an indication that such rest may be omitted In fact strict bed rest has its greatest value in the case of a young person with recently developed tuberculosis who may have few or no symptoms Complete rest treatment

then is the best means of preventing advanced cavernous tuberculosis after the cavity has formed no treatment can be quite as effective as this

Strict bed rest means confinement to bed throughout the day and night the patient not being allowed to take any steps Occasionally, when the use of a bedpan is difficult, the commode may be substituted While the patient may change his position for comfort he is instructed that the degree of rest has a definite effect in accelerating recovery and that he should avoid unnecessary moving and restlessness Usually he may be allowed to sit up in bed and feed himself but if symptoms are acute or severe even this is denied and he must be fed by a nurse *Special postures* in bed may be favored with relation to the involved lung Lying on the affected side supported with sandbags or pillows lessens the motion of the lung on that side and may promote healing On the other hand if there is a basal cavity or if the bronchi are distorted or obstructed this position may favor the accumulation and stasis of exudate and secondary suppuration, the patient is then encouraged to change his position from time to time so as to promote drainage Brock and others report some success keeping the patient flat with the foot of the bed elevated 18 inches throughout the day and night and some patients report a diminution of the amount of expectoration when in this position Quietness of the patient and limitation of respiratory movement may sometimes be favored by keeping a bag of lead shot weighing from 2 to 5 or 6 pounds on the affected side of the chest Casts braces straps and other devices have occasionally been used to limit the motion of the affected hemithorax but simpler methods seem to be just as good if the patient cooperates

The *duration* of strict rest in bed depends on the symptoms and behavior of the pulmonary lesions Constitutional symptoms such as fever may disappear soon or late and at a more gradual pace the cough and expectoration may diminish and finally cease With this the sedimentation rate of the erythrocytes and the leukocyte count may return to normal All this is favorable but does not show necessarily that adequate and durable stabilization of the lesions has occurred yet Bed rest should be continued, therefore to allow time for fibrous organization to be well initiated In general, this requires from two or three months to a year or more depending on the extent and character of the lesions To be guided alone by the symptomatic response is usually to be deceived and the patient who leaves bed prematurely usually experiences a relapse immediately or after a period of apparently good health the "false recovery which Laennec described Sufficiently effective healing of the lesions is determined chiefly by periodic roentgenographic and bacteriologic examinations When cavities have shrunken and closed as indicated by roentgenographic changes and absence of tubercl bacilli from the sputum and when infiltrative lesions have reached a point of stability as indicated by a cessation of resolution and a sharpening of the outlines of the roentgenographic shadows the patient is well on the road to recovery and everything should be done to insure that this will continue Too much physical activity or loss of rest may cause renewed inflammation about the lesions caseous degeneration of their centers and the reopening of apparently healed cavities

Since stability is a relative quality, which may be constant under conditions of bed rest but unreliable under excessive exertion, rest is not discontinued abruptly but very gradually allowing the patient to undertake mild exertions increasing by slow steps At first he may sit in a chair for fifteen minutes a day and after a week or two this may be increased gradually Then he may take a few steps or walk slowly for five minutes daily for a week or two again increasing at intervals until at the end of several months he is sitting up several hours a day and walking for perhaps thirty minutes Using the checks and guides which have been described the kind and rate of exertion are regulated according to the response of the patient and its effect on his lesions In time the patient may be walking an hour or two a day or doing some light task such as writing weaving typing or tooling leather for three or four hours daily The time required for reaching this point varies from six months in an adult with a chronic limited lesion to a year in an adolescent girl with

a freshly developed pulmonary infiltration and to longer periods for the person with more advanced disease particularly if this has been bilateral caseous and cavernous In a good many advanced cases one can hope for nothing better than relative quiescence of the disease without complete healing of the cavities and the patient must accept chronic invalidism as his lot In these when quiescence has been approximated the routine of rest is relaxed and more consideration is given to the patient s comfort granting him reasonable indulgence

The *diet* should be varied and should contain in adequate amounts the elements which are now known to be necessary for the promotion of good general health There is no proved virtue in eating excessive amounts In some cases a low carbohydrate high protein diet may be beneficial Sandler and Berke have described the effects in a carefully controlled group of patients For most patients milk is easily digestible and particularly if they are undernourished a glassful may be drunk morning afternoon and night in addition to that taken with regular meals

Fresh air has always been considered an important feature of the treatment Sleeping out may be salutary for many patients particularly young ones but there is no virtue in a frigid temperature especially when rest is hindered by weight of bed clothing

The tonic effect of *sun baths* and *artificial heliotherapy* in carefully graded doses may be helpful after the pulmonary lesions have become well stabilized and fibrotic Deleterious effects have been observed in patients with active or exudative lesions particularly when sunburn has occurred and there seems to be a danger of precipitating hemoptyses with overdosage in such cases The tonic effect of *air baths* taken on a shaded porch may be appreciated also by some patients

Drugs may be used for their symptomatic effect None have been demonstrated to have an effective or specific influence on the course of human tuberculosis Gold compounds such as sanocrysin have been used widely with questionable or sometimes damaging results The same may be said for many chemotherapeutic agents vaccines and serums The striking antibacterial effects of the sulfonamide drugs have led logically to their trial in tuberculosis While the course of the disease in experimental animals seems at times to be retarded no such definite effects have thus far been demonstrated in patients

The treatment often has to be modified or supplemented on account of the existence of complications which usually are due to tuberculous lesions elsewhere in the body These are described in the paragraphs pertaining to the given lesions

Collapse Therapy —Perfection of mechanical therapy to bring about immobilization and collapse of the lung and the good results obtained in well selected cases necessitate considering the possible usefulness of these in every case Careful judgment is required since every measure of treatment has limitations complications and potentialities of harm if improperly used In the early case of minimal extent healing under the rest regimen alone is the rule and collapse of the lung is not usually necessary It has not been proved that healing of a non cavernous lesion is accelerated by this artificial means beyond the rate to be expected from simple rest Indeed following the principle of promoting the patient s general resistance by every possible means rest treatment is not omitted even though artificial collapse of the lung may be needed also In cavitary tuberculosis there are almost always secondary bronchogenic infiltrations the prognosis is less favorable and collapse therapy therefore is indicated more often The most striking effect of the procedure is the closure and healing of cavities when rest treatment alone offers little or no prospect of accomplishing this necessary end The important mechanisms are approximation of the walls of cavities lessening respiratory motion and slowing the circulation of blood and lymph continuing until the healing process has had time to become thoroughly established

Artificial pneumothorax is induced by injecting clean air in measured amounts from a special apparatus through a hollow needle into the pleural cavity Providing the lung is not adherent the introduction of air permits the lung to retract and collapse through its own elasticity the alveolar spaces and tuberculous cavities may collapse simulta

neously In the average case, however, the stiffness of the fibrotic cavity walls, the density of surrounding lesions or the presence of pleural adhesions interfere so that in ultimately successful cases three to six months are usually required before the cavity is completely closed and tubercle bacilli disappear from the sputum Barring complications the treatment is then continued for two to four or five years depending on the extent of the lesions, in order to insure good healing After this the lung is permitted to reexpand At first the treatment is carried out by insufflating air every two or three days and later as this is absorbed less rapidly through the pleural membrane every week or few weeks the pleural pressures always being registered on a manometer connected to the pneumothorax apparatus It s important to use aseptic technic to avoid infection of the pleura The effect is observed by frequent fluoroscopic examinations and by other guides The treatment is chosen and tried in any case of pulmonary tuberculosis in which one lung is involved with cavity and infiltrations, provided a reasonable period of rest treatment alone has proved ineffective or offers no prospect of adequacy The other lung often is affected but the lesion here should be slight limited, and preferably inactive or quiescent In more advanced cases pneumothorax sometimes is undertaken as a partial aid with the hope that other measures may also be used For the control of hemorrhage in cavernous cases it is usually effective provided adhesions do not interfere In a few cases in which both lungs are affected *bilateral pneumothorax* may be induced with benefit, but good eventual results are rather meager In predominantly unilateral disease artificial pneumothorax is sufficiently effective in about one third of the cases attempted in the remainder adhesions are so extensive as to defeat the purpose Sometimes these may be severed by Jacobaeus s *intrapleural pneumolysis* using a cautery guided under direct vision through the thoracoscope introduced between the ribs Complications are encountered frequently in artificial pneumothorax Air embolism may be avoided by careful technic in the Tuberculosis Service of Bellevue Hospital it has occurred only once in every 10 000 to 12 000 thoracenteses Serofibrinous pleurisy, usually tuberculous is a frequent complication (80 to 90 per cent of the cases) As a rule this is mild and the fluid may be absorbed spontaneously If chronic adhesions develop at the base of the lung and the pneumothorax may be lost Otherwise, the visceral pleura becomes organized and fibrotic, and the lung may fail to reexpand In a minority of cases the fluid becomes empyematous and the pleural disease chronic, amyloidosis then may be a result Pleural perforation and secondary mixed infection empyema occur occasionally, more often in the active caseous forms of pulmonary tuberculosis There are other less common complications

Pneumoperitoneum induced by insufflating air into the peritoneal cavity has been tried to raise the diaphragm and lessen its motion The results have not been impressive the peritoneum may be irritated by the air and the patient may be uncomfortable

Paralysis of the hemidiaphragm by interference with the phrenic nerve is accomplished by avulsion of the nerve or by crushing or cutting it along its course Crushing (phrenemphraxis) is now used since the nerve regenerates within six or eight months and the diaphragm resumes its function this is desirable, particularly if the procedure has proved ineffective Diaphragmatic paralysis has been found effective in a limited number of cases in which there is a round thin walled, somewhat recently developed pulmonary cavity situated in the lower or middle one third of the lung not attached to the chest wall by surface adhesions It has the disadvantage in some cases of interfering with the effectiveness of cough for eliminating discharges from the bronchi particularly if thoracoplasty must be undertaken later It may also cause mild gastric disturbances and some impairment of blood circulation and ventilation of healthy parts of the lung

When less drastic measures fail or offer little promise *thoracoplasty* may be indicated Sections of ribs are removed usually from above downward the number depending on the extent of the cavernous lesion Two or more operations may be required The ribs are removed subperiosteally and eventually they regenerate partially in the collapsed position This often results in ap-

proximation of the walls of the cavity and the release of tension so that enveloping fibrosis may be effective for healing The operation is indicated in well stabilized fibroid disease of one lung in which there is a cavity which has not healed or does not promise to heal under other treatment If lesions are present in the opposite lung they should be well arrested in more desperate cases active lesions in the latter may be controlled possibly by pneumothorax Bilateral thoracoplasty has been performed occasionally but the resulting limitation of respiratory function is usually great Thoracoplasty should not be delayed if pneumothorax proves ineffective which as a rule may be determined within several months The operation may also be indicated if pneumothorax is complicated by intractable tuberculous empyema Probably 5 to 10 per cent of tuberculous patients may be helped by thoracoplastic operation By designing the operation for the individual situation the results are usually favorable in well selected cases

Another operation is the separation of the parietal pleura from the ribs and collapse of underlying lung as the parietal pleura is stripped away over the lesions The resulting space has been filled with various substances such as wax fat or muscle in recent years air has been used (*extrapleural pneumothorax*)

Distortion or obstruction of bronchi leading into tuberculous cavities may hinder drainage and cause gas to collect under tension in the cavity Suction drainage by the Monaldi technic using a catheter inserted through the chest wall may then be beneficial Untoward complications are sometimes observed and thoracoplasty is eventually necessary in most of these cases

Tuberculous lobes and lungs have been successfully resected in a few clinics but the field of this procedure is necessarily very limited and remains to be clearly defined because of the anticipated hazards

Treatment of Special Symptoms — *Cough and expectoration* traceable usually to excavating lesions of the lungs are best controlled by rest treatment The patient is instructed to wait for the mucopus to be carried by ciliary action into the trachea or larynx when it may be raised easily by gentle clearing of the throat or by slight coughing this avoids the irritation and unnecessary respiratory motion caused by frequent and futile coughing In some far advanced cases, however these symptoms are rather incessant and it is necessary to give sedatives such as codeine sulfate ½ grain at intervals of three or four hours or longer so that the patient may get sufficient rest sometimes this may be supplemented with a hypnotic at night For the distressing cough of patients who have considerable bronchitis steam inhalations perhaps with the addition of some medication like creosote or tincture of benzoin may be alleviative Expectorant cough mixtures often cause a gastric upset and are to be avoided if possible In the early morning when the patient experiences difficulty in clearing out accumulated discharges a drink of hot water or hot lemonade may stimulate the flow When the exudate accumulates in large cavities coughing sometimes is reduced by having the patient assume a posture which facilitates drainage for fifteen to thirty minutes two or three times a day In the case of a basal cavity he may hang over the bed with his head down Keeping the foot of the bed elevated 15 to 18 inches may help to prevent stagnation of exudate in cavities In some cases the cough may be referable to tuberculous lesions of the larynx or trachea and bronchi and treatment should be directed to these

Hemoptysis consisting only of slight streaks or spots of blood in the sputum requires no special treatment save rest in bed Large hemorrhages are usually traceable to cavities in which blood vessels have been laid bare by the ulcerating process Treatment is designed to arrest the bleeding and to prevent a dissemination of the infection in the lungs by aspiration of contaminated blood The patient should be in bed and in order to restore calm and quiet he may be reassured justifiably that the bleeding will subside Violent coughing favors aspiration of the blood into healthy alveoli and if the patient is unable sufficiently to restrain the impulse codeine sulfate ¼–1 gr may be given hypodermically Morphine is seldom indicated and then only in small doses ⅛–⅙ gr Too much sedation depresses the reflexes unduly and may permit

the retention of clots in the bronchi, which is undesirable For a day or two after the initial hemoptysis, dark clots may be expelled or fresh bleeding may recur, usually in diminishing amount If the hemorrhages are large or frequently repeated especially in cases in which the disease is predominantly unilateral artificial pneumothorax is often indicated to relax the lung and with it the bleeding vessel, this, as a rule is effective Usually, however pneumothorax is postponed for a few days or longer until accumulated blood has been cleared from the air passages since this lessens the possibility of acute pneumonic reactions and serofibrinous pleurisy after the pneumothorax If pneumothorax fails other forms of collapse therapy may be considered in emergencies occasionally thoracoplasty or extrapleural pneumothorax is indicated without delay Diaphragmatic paralysis is less effective However most hemoptyses subside after the loss of a small or moderate amount of blood and collapse of the lung may then be determined according to the usual indications During and for a few days after the hemoptysis, the patient is given a soft or light diet according to his desires and it is not necessary usually to restrict this to fluids Blood may be swallowed and thereby excite nausea and vomiting If there is constipation a saline cathartic may be given The patient is encouraged to lie on the affected side but during the waking hours he may change his position from time to time since this aids in expelling clots of blood Sometimes the patient goes into mild shock during the hemoptysis This is treated by keeping him warm and giving him warm drinks and if necessary infusions of glucose in solution If there are small frequently recurrent bleedings transfusion of 200 to 300 cc of fresh blood may be helpful Numerous drugs such as atropine nitroglycerin horse serum and calcium have been given to control hemoptyses but these seldom prove efficacious since the coagulating properties of the blood are not disturbed When bleeding is continuous though slight intravenous injections of calcium gluconate sometimes seem to be helpful but the effect of such measures is always difficult to judge In certain cases the prothrombin content of the blood may be low the administration of vitamin K is thought by some to be helpful in such conditions

Dyspnea of sudden onset usually is due to acute pneumothorax or pleurisy and is treated accordingly In advanced fibroid cases the symptom may become aggravated during attacks of acute bronchitis or bronchopneumonia when oxygen therapy is indicated for relief

Pain in the chest is traceable most often to pleuritic involvement, strapping with adhesive plaster may give relief

Night sweats occur most often in advanced febrile cases and are relieved usually by rest in bed and proper nursing Drugs such as atropine or agaricin have little effect The patient should not be covered too heavily with bed clothes and the room should be airy and cool Alcohol rubs or baths before retiring are helpful After the sweat the clothing should be changed and patient should be given an alcohol rub

Secondary anemia is treated by a good general diet and, if necessary the addition of ferrous sulfate Often the most effective measure is the proper treatment of the complicating intestinal tuberculosis

Maintaining Arrest and Avoiding Relapse —In many advanced cases of tuberculosis the physician must recognize the impossibility of complete arrest of the disease and strive only to alleviate symptoms But when there is a prospect of returning the patient to useful life it is important to estimate when treatment has been sufficient to assure stability of the disease in the situations he is obliged to face later

According to the standards of the National Tuberculosis Association the disease is considered *arrested* when the lesions have remained apparently healed tubercle bacilli have not been demonstrable and the patient has been symptom free under conditions of moderate physical activity for at least six months Since the lesions still harbor viable tubercle bacilli and relapse is possible the gains are to be maintained and consolidated during the next several years Experience shows that if the patient goes through two years with continuing arrest the chance of relapse later is greatly minimized During this time close and systematic medical observation and advice are very important, as is the cooperation of the patient in follow

ing faithfully a prescribed daily routine In most successfully treated cases six months to a year of 'arrest should elapse before the patient returns to work During the interval as far as practicable his daily schedule of activity should be increased gradually until it approximates that which he expects to continue at work Patients who have followed light or sedentary occupations usually do best in returning to the same particularly if the employer is willing to make some concessions pending complete rehabilitation One-half day's work may be safe at first to be gradually increased during the following months or years Other patients often have to be educated for a new occupation since laborious work under unfavorable conditions is always to be interdicted Institutions like the Papworth Colony and Preston Hall in England the Altro Work Shop in New York City and the Potts Memorial Institute at Livingston N Y have been instrumental in rehabilitating many patients who could not return immediately to conditions of competitive employment but who responded well under sheltered conditions and the humane skilful supervision afforded in these places there is a great need for more of them If the patient is so unfortunate as to be obliged to return to his work and to resume his social and domestic responsibilities without this easy transition he is likely to become ill again and this is followed too often by his complete demoralization the disruption of his family and his dependence on public relief —a great waste in the long run

Since the diagnosis of tuberculosis usually is not made until the disease is advanced and treatment often is postponed or inadequately administered and since proper rehabilitation is not generally and scientifically provided fully 50 per cent of the patients treated in sanatoria have relapses after discharge The picture is entirely different when the disease is diagnosed in its incipiency treatment administered promptly and properly and after arrest a normal life is resumed gradually under skilled guidance most of these patients live a normal span of years and die of some other cause Avoidance of relapse therefore is contingent mostly upon fulfilling these conditions

Periodic medical supervision is indicated indefinitely after recovery At first the patient should be seen once a month and during this time he should be questioned about symptoms the sputum should be searched for tubercle bacilli and a roentgenogram should be made for comparison with those previously accumulated Continued good general health absence of tubercle bacilli and unchanging roentgenographic shadows (except perhaps for slight further contraction of the fibrotic lesions) permit as a rule continuation or expansion of the daily routine After three or four months the interval between examinations may be gradually lengthened but for the first two or three years the patient should be observed in this way every three to six months and afterward at least once a year The appearance of symptoms should always be the occasion for medical examination to determine the cause

TUBERCULOSIS IN CHILDREN

Certain peculiarities of tuberculosis in children deserve special mention In early infancy the disease may be of grave significance lymphohematogenous dissemination may occur ending fatally or leading to the establishment of multiple systemic lesions The latter may become destructive at once or after a short or protracted period of latency There is sound evidence that the avoidance of infection in early childhood goes far toward avoiding chronic tuberculosis in adulthood Between early childhood and adolescence there is relatively little danger of death from tuberculosis though infection may be acquired (See Figs 27 and 28)

The customary distribution of lesions following primary infection in childhood helps to direct diagnostic investigations While the important lesions are found most often in the chest these as a rule are not of the ulcerative excavating parenchymatous type The usual predominance in the mediastinal tracheobronchial and bronchopulmonary lymph nodes explains the failure to discover the lesions by physical examination unless they are extensive X ray examination therefore is just as important as or even more important than in later life Since

recently established lesions are more likely to be progressive the greater implications of the tuberculin test in children are obvious A positive test in an infant is synonymous with recent infection and with active and potentially serious disease and should arouse suspicion that there may be an active source case in the household While children may suffer occasionally from ulcerative tuberculosis of the lungs clinical manifestations are referable much more often to the caseous masses in the mediastinum or the lesions which have been disseminated from this source by way of the lymph and blood stream Consequently, the symptoms of a tuberculous mediastinal tumor are much more common in children as are secondary pulmonary effects resulting from pressures on the bronchi or ulcerations into them Similarly, one must be on the alert to detect systemic lesions varying from generalized miliary tuberculosis to isolated and perhaps latent lesions in various organs and tissues

Treatment —Treatment of the tuberculous infant is not very promising since uncontrollable factors like the size of the infecting dose of bacilli and the immediate inflammatory response of the lung and lymph nodes largely determine the fate of the victim The situation is in no way comparable to that of the adult whose life is threatened by the consequences of an excavating lesion in the lung which may be controlled by artificial pneumothorax In later childhood the greater tendency to spontaneous limitation of the infection becomes increasingly apparent Treatment then may be directed with greater promise to enhancing general resistance by a proper routine of rest and good nutrition, localized lesions may be treated with appropriate measures such as immobilization for a tuberculous joint collapse of a cavity bearing lung or excision of a tuberculous lymph node

The child with a positive tuberculin test but no demonstrable tuberculous lesion or only several isolated calcified lesions should have a roentgenogram of the chest once a year particularly as he approaches and enters adolescence but no other treatment is indicated unless a new lesion appears The child with demonstrable lesions obviously of recent origin and of a fresh inflammatory type should be treated just as an adult with an early pulmonary infiltration

J Burns Amberson Jr.

GENERALIZED LYMPHOHEMATOGENOUS FORMS OF TUBERCULOSIS

Acute Generalized Miliary Tuberculosis —The disease occurs most frequently in young children or infants and occasionally in adult life The patient may have been in perfectly good health previously or may have had some clinical or other demonstrable evidence of tuberculosis such as roentgenographic signs of mediastinal lymphadenitis The onset may be abrupt with chilliness prostration aching in the muscles headache and drowsiness or gradual with malaise weakness and fatigue for a period of a few days or a week before the patient becomes prostrated The temperature may rise at once to 103° or 104° F in the afternoons or attain this level gradually during a week or so Night sweats may be profuse the soft tissues waste rapidly and the patient is overcome by weakness Localizing symptoms depend on the predominant distribution of miliary tubercles Dyspnea and cyanosis may become pronounced because of the extensive and rapid invasion of the lungs but there is usually no cough or only a slight hacking In other cases peritoneal symptoms such as pain distention and constipation may predominate Effusions may accumulate in the serous cavities with the well known clinical manifestations of their presence if they are profuse The clinical course may resemble that of typhoid fever but the onset is usually more insidious in miliary tuberculosis rose spots do not appear and diarrhea is usually not a feature

Physical examination initially shows only the general effects of the toxemia After a week or more fleeting rales may be heard in the lungs later numerous and persisting fluid may be demonstrated occasionally in the pleura or peritoneum less often in the pericardium The spleen becomes palpable in only a minority of the cases Uncommon findings include superficial lymphadenopathy and tubercles in the ocular fundi The roentgenogram of the chest is indeterminate at

first but usually shows characteristic stippling of the pulmonary fields within a week or two The leukocyte count remains normal or becomes elevated to 15 000 or 20 000 seldom more Death occurs usually within six to eight weeks occasionally with meningeal involvement

Subacute Forms of Lymphohematogenous Tuberculosis —These likewise are observed most often in the early ages but occasionally also in adults particularly Negroes Tubercle bacilli enter the lymph and blood streams usually from a lymphatic focus perhaps at recurring intervals The number of lesions established in various organs is only moderate and since the patient does not die soon time is sufficient to permit further local development with degeneration or partial healing Many bacilli are picked up by the lymphatics and come to rest in various regional nodes The lungs are frequently involved the lesions being particularly prominent in the upper parts The spleen kidneys liver and serous membranes often participate

The variety of clinical manifestations is great but some are fairly constant The patient may have obscure fever which has persisted for days or weeks without other obvious symptoms except loss of weight malaise and fatigue In time peripheral lymphadenopathies may become apparent as in the auricular cervical axillary epitrochlear and inguinal regions A roentgenogram of the chest may show only widening of the upper mediastinum from the lymphatic lesions The spleen may become palpable within a few weeks or months Other patients with similar fever reveal evidence only of an effusion in the pleura peritoneum or perhaps in several or all of the serous cavities Still others may be found to have genito urinary tuberculosis and occasionally papulonecrotic tuberculides of the skin give the first clue to the identity of the fever Multiple lesions in the bones and joints and in the eye may be associated some may become ulcerous or fistulous

Probably a majority of these patients die within three to six months but a few survive longer and rather seldom one may live for many years harboring disseminated partly calcified lesions chiefly in the lymph nodes Progressive bilateral ulcerative pulmonary tuberculosis is often the predominant lesion toward the end

Latent and Chronic Forms of Lymphohematogenous Tuberculosis —It is not uncommon at autopsy to find tubercles originating obviously in lymphohematogenous dissemination of the infection perhaps many years before distributed in such structures as the spleen liver kidneys lungs and lymph nodes These may be small even microscopic gray tubercles isolated in fibrous capsules Others are represented by encapsulated round calcified nodules sometimes they are so discrete and nonspecific in appearance that they are mistaken for simple phleboliths Reichle and Work found such lesions in 20 1 per cent of 452 routine autopsies at the Cleveland City Hospital, and upon further investigation demonstrated that most of them were tubercles While these foci may never assume clinical significance they are latent depots from which local active disease may develop after weeks months or even many years

Chronic disseminated lymphohematogenous tuberculosis may be visualized as a stage between the subacute and the latent forms The chronic form may be due to the slow evolution of mild infection disseminated during or shortly after the development of the primary complex to the reactivation of old systemic lesions which may have remained latent for years or to renewed hematogenous infection from old foci which have become reactivated The character and distribution of the lesions may be manifold and in some cases one may see granulomatous and caseous lesions ulcers and fistulas in one or more joints in the lymphatic system skin eyes or in the abdomen or thorax Whether they are numerous few or single is largely a matter of chance depending on factors of infection resistance age and location of previous lesions Probably the most common clinical picture is mild chronic tuberculosis involving various lymph nodes possibly one or more of the serous surfaces and the lungs Mild exudative or plastic inflammations may appear and recur in the serous membranes and there may be slight or moderate recurrent swelling of lymph nodes which on roentgenographic examination appear partially calcified

Involvement of the lungs usually appears

as lightly distributed nodular, fibroid infiltration, most pronounced at the apices and at the hilar levels which later may be associated with varying degrees of interstitial fibrosis secondary emphysema and chronic adhesive pleurisy The symptoms usually are vague, the patient may be chronically undernourished and frail and may experience periods of low fever for weeks or months Later he may develop dyspnea and slight or mild cyanosis on account of the fibrosis and emphysema The cough if any is slight and hacking and there is only a little mucoid expectoration unless the pulmonary lesions go on to ulceration Recovery or improvement may take place slowly leaving behind scars and secondary changes which may be harmless or cause mechanical or functional disturbances On examination, the lungs reveal signs of emphysema, with no rales or only a few fine ones scattered mostly in the upper halves The roentgenogram however, usually discloses the suggestive finely nodular and strand like densities radiating from the hila particularly toward the apices and may also show the pleural thickening and signs of emphysema The discovery of other lesions in the skin kidney epididymis or elsewhere may help to establish the diagnosis In some of these cases especially in elderly males the chronic debility may raise the question of malignant disease with metastasis particularly if the pulmonary lesions are atypical and associated with a serous effusion in the pleura Tuberculosis is not an uncommon cause of such manifestations at this age and should always be considered

Tuberculosis of the Serous Membranes—Any of the serous membranes may become infected usually singly but sometimes in combination The pleura is most commonly involved secondly the peritoneum less often the pericardium The way of infection is by direct extension from some contiguous tuberculous lesion or by the blood or lymph streams The lesions appear as isolated tubercles or as fibrinous or serofibrinous inflammations The tubercles may be few and isolated or numerous and disseminated through the membrane Fibrinous changes usually are rather limited while serofibrinous inflammations involve the whole membrane which is edematous and red The serous exudate may be absorbed leaving behind a rough fibrinous coating of the serosa and fibrinous deposits may become partially or completely resolved As a rule, however, some of the endothelial lining is destroyed, granulations develop and eventually, are transformed into fibrous tissue, adjacent surfaces may be bound together by firm adhesions in which lymph and blood vessels may develop Occasionally, especially if the inflammation is serofibrinous the process becomes chronic In relatively few cases, the effusion becomes purulent deep inflammation and granulomatous thickening of the serosa occur and this may undergo caseous degeneration Subsequent organization and fibrosis leave behind permanent thickening and adhesions of the membranes with distortions and retractions of adjacent structures The serous or purulent exudate may become loculated After some years if this is absorbed incompletely or very slowly the organizing walls of the pockets become infiltrated with calcium salts Calcification of the pleura is seen occasionally, calcification of the pericardium less often, calcification of the peritoneum very rarely

Tuberculosis of the Pleura—One or both pleurae may be affected The commonest form is fibrinous pleurisy and this usually overlies a pulmonary lesion Serofibrinous pleurisy develops in approximately 5 per cent of all cases of pulmonary tuberculosis it may also be a manifestation of generalized hematogenous tuberculosis This is probably the case if both pleurae or other serous membranes are involved simultaneously or in close succession Tuberculous empyema is uncommon except as a complication of pneumothorax natural or induced in which effusions are frequent the most serious forms are caused by ulceration and perforation of the pleura secondary to ulceration of an underlying pulmonary lesion Isolated fibrous adhesions may be left behind but after serofibrinous pleurisy heals, the pleura becomes widely or totally adherent almost always and if the inflammation was severe the resulting organization and thickening may cause retraction of the mediastinum diaphragm and chest wall The same is true to a more pronounced degree of healing tuberculous empyema

Fibrinous pleurisy may occur without lo

calizing symptoms but in a few cases is accompanied by the development of a severe sharp pain in the side immediately over the area of involvement or referred along the segmental distribution of the sensory nerves thus diaphragmatic pleurisy may cause pain in the trapezius ridge and in the upper hypochondrium The pain is usually aggravated by breathing and may last for a few hours to several days occasionally longer General symptoms of lassitude, possibly with low afternoon fever may last for a few days to several weeks

Serofibrinous pleurisy may develop as a complication of previously recognized pulmonary tuberculosis in which case the clinical onset may not be distinguishable from the exacerbation of a pulmonary lesion In other cases the presence of pulmonary tuberculosis may be unknown previously or the lungs may be found clear Small effusions may collect and disappear unknown to the patient The onset may be insidious with malaise and fever rising gradually to 101° or 102° F or it may be acute with a sudden sharp pain in the side chilliness malaise and fever rising quickly to 104° or 105° F The subsequent course may continue mildly or acutely The effusion may be small and become absorbed within a couple of weeks with complete subsidence of symptoms In the acute cases however high fever frequently continues daily for four to six weeks after which defervescence by lysis follows During this time the patient may lose 10 20 or more pounds in weight, become weak and have severe sweats Small effusions cause no local symptoms but large collections may produce dyspnea and cyanosis on account of the displacement of the heart, blood vessels and lung Convalescence usually starts after four to six weeks but occasionally is delayed for three to six months the fluid then becomes slowly absorbed leaving behind varying degrees of thickening and retraction

DIAGNOSIS —The diagnosis of dry or fibrinous pleurisy is made by detecting a friction rub or pleural crepitus but this may disappear soon or be entirely lacking The diagnosis of serofibrinous pleurisy is indicated by the physical and x ray signs of a basal ef[illegible] possibly with associated signs of [illegible]berculosis and of displacement of the heart. In the early stages thoracentesis yields clear straw-colored fluid which has the characteristics of an exudate and contains cells of a mononuclear occasionally polymorphonuclear type infrequently it is sanguinolent Tubercle bacilli usually are not discovered by microscopic examination because they are rather scarce. If possible 500 cc or more of fluid should be treated by centrifugation and the sediment inoculated on culture media and into a guinea pig the organisms are usually demonstrated in this way However, the failure to find tubercle bacilli even on inoculation does not necessarily exclude tuberculosis

TREATMENT —The treatment of fibrinous or serofibrinous pleurisy is determined by the severity of the process and of any associated lesions As a rule, localized fibrinous lesions do not require more than a few weeks of rest treatment The treatment of serofibrinous pleurisy is more important If the patient has pulmonary disease as well the pleurisy is regarded as a problem in the general treatment already described If no pulmonary lesions are demonstrated it must be remembered nevertheless that 20 to 30 per cent of these patients fall ill with pulmonary tuberculosis or some other form of the disease within five years Therefore the case should be treated as one of active tuberculosis with rest in bed for one to three months after the acute symptoms have subsided to be followed by another three to six months convalescence probably in a sanatorium. The indications for withdrawing the fluid from the pleural cavity are (1) at the start, for diagnosis (2) to relieve respiratory embarrassment from mechanical displacements (3) to dispose of any residual collection after the febrile symptoms have subsided and absorption seems to be too slow (4) to visualize the underlying lung if parenchymal lesions are suspected For the last mentioned purpo e 100 to 200 cc of air are [illegible] with a pneumothorax apparatus during evacuation of the fluid The [illegible] parenchyma may then show much more clearly in the roentgenogram. O[illegible] pneumothorax should be avoided since [illegible] interferes with healing and retards [illegible] of the pleural surfaces The prognosis of uncomplicated tuberculous pleurisy with effu ion is excellent if sufficient rest treatment

as lightly distributed nodular, fibroid infiltration, most pronounced at the apices and at the hilar levels which later may be associated with varying degrees of interstitial fibrosis, secondary emphysema and chronic adhesive pleurisy The symptoms usually are vague, the patient may be chronically undernourished and frail and may experience periods of low fever for weeks or months Later he may develop dyspnea and slight or mild cyanosis on account of the fibrosis and emphysema The cough, if any is slight and hacking and there is only a little mucoid expectoration unless the pulmonary lesions go on to ulceration Recovery or improvement may take place slowly leaving behind scars and secondary changes which may be harmless or cause mechanical or functional disturbances On examination the lungs reveal signs of emphysema, with no rales or only a few fine ones scattered mostly in the upper halves The roentgenogram however, usually discloses the suggestive finely nodular and strand like densities radiating from the hila particularly toward the apices and may also show the pleural thickening and signs of emphysema The discovery of other lesions in the skin kidney, epididymis or elsewhere may help to establish the diagnosis In some of these cases especially in elderly males the chronic debility may raise the question of malignant disease with metastasis particularly if the pulmonary lesions are atypical and associated with a serous effusion in the pleura Tuberculosis is not an uncommon cause of such manifestations at this age and should always be considered

Tuberculosis of the Serous Membranes—Any of the serous membranes may become infected usually singly but sometimes in combination The pleura is most commonly involved secondly the peritoneum less often the pericardium The way of infection is by direct extension from some contiguous tuberculous lesion or by the blood or lymph streams The lesions appear as isolated tubercles or as fibrinous or serofibrinous inflammations The tubercles may be few and isolated or numerous and disseminated through the membrane Fibrinous changes usually are rather limited while serofibrinous inflammations involve the whole membrane which is edematous and red The serous exudate may be absorbed leaving behind a rough fibrinous coating of the serosa and fibrinous deposits may become partially or completely resolved As a rule, however, some of the endothelial lining is destroyed granulations develop and eventually are transformed into fibrous tissue adjacent surfaces may be bound together by firm adhesions in which lymph and blood vessels may develop Occasionally, especially if the inflammation is serofibrinous the process becomes chronic In relatively few cases the effusion becomes purulent deep inflammation and granulomatous thickening of the serosa occur and this may undergo caseous degeneration Subsequent organization and fibrosis leave behind permanent thickening and adhesions of the membranes with distortions and retractions of adjacent structures The serous or purulent exudate may become loculated After some years if this is absorbed incompletely or very slowly the organizing walls of the pockets become infiltrated with calcium salts Calcification of the pleura is seen occasionally calcification of the pericardium less often calcification of the peritoneum very rarely

Tuberculosis of the Pleura—One or both pleurae may be affected The commonest form is fibrinous pleurisy and this usually overlies a pulmonary lesion Serofibrinous pleurisy develops in approximately 5 per cent of all cases of pulmonary tuberculosis, it may also be a manifestation of generalized hematogenous tuberculosis This is probably the case if both pleurae or other serous membranes are involved simultaneously or in close succession Tuberculous empyema is uncommon except as a complication of pneumothorax natural or induced in which effusions are frequent the most serious forms are caused by ulceration and perforation of the pleura secondary to ulceration of an underlying pulmonary lesion Isolated fibrous adhesions may be left behind but after serofibrinous pleurisy heals the pleura becomes widely or totally adherent almost always and if the inflammation was severe the resulting organization and thickening may cause retraction of the mediastinum diaphragm and chest wall The same is true to a more pronounced degree of healing tuberculous empyema

Fibrinous pleurisy may occur without lo

of air through the tube into the pleura Effusion is kept down by aspiration to avoid drainage through the bronchopleural fistula into the lungs Since infection usually continues and healing of the bronchopleural fistula seldom occurs spontaneously thoracotomy for drainage is usually necessary and eventually extensive thoracoplasty The fatality rate is high because of the seriousness of the complication and frequently because of the extent of the underlying pulmonary tuberculosis

Tuberculosis of the peritoneum may be the result of hematogenous infection or of extension from local lesions such as retroperitoneal lymphadenitis or salpingitis Fibrinous inflammation in the visceral peritoneum at the site of intestinal ulcers is a common finding General involvement may be miliary, serofibrinous or plastic and adhesive Serofibrinous peritonitis may have an acute or insidious onset with constitutional symptoms like those described for serofibrinous pleurisy Abdominal pain and tenderness are usually slight or moderate occasionally very intense Constipation is a common symptom Diarrhea usually is an indication of intestinal ulcerations but the combination of these with generalized peritonitis is not common Abdominal distention may be great due to ascites and tympanites but in other cases the wall is spastic and scaphoid Signs of fluid may be difficult to demonstrate if the accumulation is small As adhesions develop the exudate may become loculated in pockets and the omentum and intestine matted

Exudative peritonitis is most common in children and young adults but may occur even in old people it is observed more often in Negroes than in whites and in females than in males Occasionally it is a complication of cirrhosis of the liver Except when it is such a complication or a part of generalized tuberculosis the prognosis for healing is good provided general rest treatment is instituted early and carried out long enough Mechanical symptoms may require evacuation of the fluid some prefer to do this by a small surgical incision Laparotomy is unnecessary in most cases Formerly, exposure of the diseased peritoneum to the air was supposed to be beneficial but this is doubtful In female patients tuberculosis of the fallopian tube may prolong the peritonitis and favor chronicity in such cases salpingectomy may be indicated After the disease becomes quiescent carefully graded heliotherapy may have a beneficial tonic effect

Plastic adhesive peritonitis usually is a later development of fibrinous or serofibrinous inflammation The serous surface becomes involved in a chronic granulating and organizing process which results in more or less extensive adhesions and thickening Fibrous contraction may produce narrowing of the lumen of the bowel the coils of which may be bound together in large inseparable tangles Between the hyperplastic and caseous lesions tuberculous exudate sometimes purulent, may be pocketed Abdominal examination may reveal irregular masses of involved omentum matted intestine caseous deposits or enlarged lymph nodes These may be numerous or confined to a single section such as the right lower quadrant surrounding the cecum Aside from the manifestations of chronic toxemia local symptoms may become distressing on account of the fixation and stenosis of the bowel There may be constipation obstipation or occasionally obstruction Rarely the intestine is perforated and tuberculous pus may drain from the peritoneum into it Treatment is general and symptomatic unless the disease is localized and accessible such as a hyperplastic process in and surrounding the cecum this may be resected surgically Postoperative abdominal fistulas which may be fecal are not uncommon

Tuberculosis of the pericardium may represent an extension from the pleura in which case the lesions are usually of a localized fibrinous hyperplastic or adhesive character giving rise to few or no symptoms Serofibrinous pericarditis is observed most often in association with acute or subacute lymphohematogenous dissemination of the infection Aside from the manifestations of toxemia symptoms and signs referable to tamponade of the heart may be found the embarrassment may be relieved by paracentesis Because the infection often is systemic the prognosis for recovery usually is poor The effusion may continue reaccumulating and after three to six weeks loculation may occur because of the formation of

is given Because of the hazard of pulmonary tuberculosis developing later, x ray examination of the chest every six to twelve months is advisable for any patient who has had tuberculous pleurisy

TUBERCULOUS EMPYEMA is related usually to some peculiar situation such as pleural ulceration and rupture or artificial pneumothorax and is considered in this connection Serous effusions develop in artificial pneumothorax in more than 90 per cent of the cases where the treatment is continued for months These may be absorbed rapidly, causing few or no symptoms In other cases the effusion becomes chronic and may undergo other changes A rich admixture of fibrin may collect in flakes threads or balls and the content of mononuclear cells may increase to 5000 or more per cubic millimeter In other cases there is a large output of polymorphonuclear leukocytes which rapidly undergo degeneration giving the effusion at first a cloudy appearance and later a thick light yellow or greenish creamy consistency Tubercle bacilli may be demonstrable easily microscopically and may appear in large clumps A thick coating of fibrin is deposited on all the pleural surfaces later to be transformed into granulation and fibrous tissue Unless the exudate is absorbed early organizing pleurisy enveloping the collapsed lung may bind this down and prevent its reexpansion Occasionally the empyema becomes thin and serous and is absorbed but more often chronic inflammation continues and generalized amyloidosis may result Thoracotomy for drainage is contraindicated because of the danger of introducing secondary infection and creating a permanent sinus of the thoracic wall Unless the lung reexpands readily while the fluid is removed by thoracentesis or by absorption extensive thoracoplasty is required to obliterate the pleural space approximating the surfaces so as to allow adhesion and healing

PNEUMOTHORAX in tuberculous cases is related either to the ulceration of a subpleural caseous focus or to the rupture of a subpleural bulla which has developed secondary to the fibrosis In the latter event the lung collapses but as a rule the pleura does not become infected nor is there any effusion The tear heals readily and the lung expands within several months In the former event however tubercle bacilli are invariably discharged into the pleura through the fistula, acute serofibrinous pleurisy develops and often goes on rapidly to tuberculous empyema Secondary infection with streptococci staphylococci or pneumococci is common creating a mixed infection empyema After the lung collapses the fistula may operate as a valve mechanism permitting the accumulation of air under great tension in the pleural space The fistula is usually chronic and seldom heals except after operative intervention Consequently the pleura is continually reinfected Sometimes too the pleural effusion or empyema escapes through the fistula into the lung on the same or opposite side causing acute tuberculous bronchopneumonia

The symptoms of pneumothorax may develop in a known tuberculous patient or in one who appeared healthy previously As a rule a sudden sharp tearing pain in the chest is experienced followed quickly by increasing shortness of breath and cyanosis The patient seldom loses consciousness but occasionally this accident may be the cause of sudden death In other cases the event is symptomatically silent particularly if the pleural perforation is tiny and the lung is partially anchored by adhesions which prevent its complete collapse in the latter case the pneumothorax is detected as a localized pocket If there is no infection the symptoms may soon subside with or without thoracentesis for the withdrawal of air and the patient experiences no difficulty while the lung reexpands With infection the symptoms of serofibrinous pleurisy develop acutely and examination reveals hydropneumothorax with varying degrees of displacement of the yielding mediastinum diaphragm and chest wall Thoracentesis at the start reveals a clear or cloudy effusion in which tubercle bacilli may be found alone or in combination with pyogenic organisms

Treatment is designed at first to relieve the acute mechanical displacement which is done by aspirating gas from the pleura at required intervals or it may be withdrawn continuously through an indwelling needle connected with an aspirating apparatus or to a rubber tube the other end of which is placed in a pan or bottle of water beneath the bed This mechanism prevents reflux

these is in proportion to the amount of caseous degeneration which occurred previously

Cervical lymphadenitis is a common form but in the United States has become much less prevalent since the early nineteen hundreds The disease which was known in earlier times as scrofula or king s evil has been reduced through the elimination of tubercle bacilli from milk and the prevention of massive infection in childhood The lesions may be confined to one or several nodes or may encircle the neck anteriorly from ear to ear The upper deep cervical nodes are most frequently affected as a rule the lesions are more pronounced on one side Infrequently the acute swelling is so marked as to impede the motion of the neck and to displace the trachea If the onset is insidious the lumps may be discovered purely accidentally Tenderness is slight or moderate unless the overlying tissues become involved The skin usually appears healthy but may become red tender and gradually thinned out until perforation occurs A thick or nummular purulent discharge follows and drainage may continue for a long time Neglect of the condition may result in fistulas in various parts of the neck and in the upper thorax Rest treatment if instituted early usually leads to healing of the lymphadenitis The swelling may disappear entirely or small nodes may persist with calcareous centers demonstrable by x ray Surgical treatment may be indicated when there is extensive abscess formation or if the involved nodes become so numerous and large that healing cannot be expected under simpler treatment Heliotherapy after the acute stage has passed may aid in the healing of fistulous tracts and general heliotherapy is thought by some to be helpful in chronic cases X ray therapy is considered by many to have a place especially after fistulae and scrofuloderma have developed However this treatment probably when too intensive has been known to accelerate the necrosis of inflamed and caseous nodes

Abdominal lymphadenitis may be part of a generalized infection or result from lesions in the intestine peritoneum or other adjacent organs Usually there are no specifically localizing symptoms but when the involvement is moderate or extensive vague abdominal pain constipation and indigestion may be complaints Sometimes the condition simulates chronic appendicitis Advanced wasting disease in infants and young children is known as *tabes mesenterica* Unless the lesions originally were extensive or part of generalized tuberculosis the tendency to heal is striking

Tuberculosis of the Urinary Tract.— The kidney is the most frequent site, the infection usually being hematogenous In the males the infection sometimes extends to the urinary tract from the genitals The disease is much more prevalent in adults than in children and is observed two to four times as frequently in males as in females The finding of microscopic tubercles in the kidneys is common at autopsy but gross lesions are detected in 10 per cent or less of all cases of chronic pulmonary tuberculosis The disease often occurs in patients who have never suffered from pulmonary disease the presumption being that the infection was carried from a lymphatic focus usually mediastinal Renal lesions may be latent for a long time before causing clinical symptoms The early lesion is usually in or near the glomeruli and bacilli may pass from this through the tubules to the papilla Caseation and ulceration may be limited or extensive resulting in the formation of small fistulas and the discharge of bacilli into the renal pelvis and ureter These more resistant structures also may be invaded then Often the kidney becomes more or less excavated Occasionally the caseous lesions may be encapsulated or the ureters become sealed off then calcareous changes may develop The bladder may be infected with bacilli carried in the urine tubercles and ulcers about the ureteral orifice appear and if the invasion is wide later fibrous shrinkage may reduce the capacity greatly Calcification of the bladder is rare Destructive renal tuberculosis at first is usually unilateral Bilateral disease may result from hematogenous or lymphogenous infection and possibly from reflux of urine from the tuberculous bladder

The symptoms include polyuria hematuria pyuria dysuria and strangury but at the inception renal tuberculosis usually is symptomless Similarly physical examina

fibrinous adhesions Caseation is observed occasionally, especially in Negroes and this may extend into the myocardium In the few cases of recovery the layers of the peri cardium may adhere completely and in time the shrinkage may lead to chronic constrictive pericarditis with functional impairment In this disabling situation the operation of cardiolysis may effect partial or complete relief in 60 per cent of the cases (Heuer and Stewart) Occasionally the pericardium be comes calcified

Tuberculosis of the Lymph Nodes — Lymph nodes may be infected by tubercle bacilli entering the lymphatic stream from a lesion in the tributary region or arriving by way of the blood stream Most often the lesions are limited to a single chain frequently the mediastinal system However, in generalized hematogenous forms of tuberculosis multiple scattered lymphadenopathies are demonstrated commonly in the superficial and deep chains The lesions may appear as acute subacute or insidious inflammatory swelling of the nodes with grad ual caseation and necrosis Periadenitis and agglutination with adjacent nodes may fol low, later liquefaction rupture and slough ing of the contents through the overlying tissues, particularly in the case of superficial involvement As the inflammation subsides, calcification of the caseous residues may de velop slowly during a period of years and the lesions may remain as permanently en larged firm usually discrete nodes Some times chronic fistulas usually superficial persist and these may burrow widely causing extensive degeneration of the skin and sub cutaneous tissues (scrofuloderma) More often lymphadenitis is of a mild hyperplastic type with only a minimum of caseation The lesions may be chronic or they may subside and become reactivated repeatedly after long or short intervals of time without any evi dence of liquefaction or sloughing Chronic caseous lymphadenitis particularly in the mediastinum is a potential source of danger even after long periods of latency Despite partial calcification these lesions may be the source of disseminations in childhood in adolescence and sometimes even in late adult life I have seen fatal tuberculous pneumonia in a woman of seventy caused by the rupture into the bronchus of a caseous node In the chronic systemic forms of tuberculosis the lymphatic system may harbor most of the lesions and account for the protracted ill health including exacer bations of low fever from time to time

Mediastinal and bronchopulmonary lymphadenitis is observed most often in young children following the primary infection Constitutional symptoms may be mild or entirely lacking Massive lesions may pro duce pressure giving a variety of symptoms such as stridulous cough simulating whooping cough constant or intermittent wheezing respiration sometimes simulating asthma less commonly stridor, dyspnea and cyan osis Localized pressures on the bronchi may irritate and compress the tube resulting in collapse of the lobe or of the lung or the development of nonspecific suppurative bronchopneumonia and possibly bronchiec tasis Perforation of the nodes through the trachea more often the bronchi may occur soon or after a lapse of many years dis charged tubercle bacilli may then be aspir ated into the lung causing tuberculous bron chopneumonia Calcified nodes similarly may ulcerate through the bronchi (bron cholithiasis) Physical examination usually is not helpful unless the mass is very large then it may be suspected by dulness and altered breath and voice sounds extending beyond the spine or sternum on one or both sides The roentgenogram reveals the lesions unless they are small and concealed by other structures the shadows include bulbous en largements of the hilum widening of the mediastinal density and the round and oblong homogeneous or granular opacities of calcification With few exceptions the tuberculin test is positive and often there are typical lesions also in the lungs or elsewhere Occasionally physical signs and symptoms of bronchial stenosis or of tracheal and venous obturation may be elicited The treatment is the general hy gienic rest regimen together with pediatric supervision in the case of children X ray therapy has been tried but usually is ill ad vised because of the possibility of aggravat ing caseation The same may be said of tu berculin therapy Under rest treatment mas sive enlargements may gradually subside eventually leaving very little trace or pos sibly only calcified residues The extent of

may appear in the urine While rest treatment is indicated in these cases the lesions usually run a chronic course and the prognosis for ultimate healing is not good Therefore after the acute inflammation has subsided surgical resection should be considered especially if the demonstrable lesions are limited and unilateral Removal of an epididymis for instance may prevent further invasion of the seminal tract The results generally are good

Tuberculosis of the Meninges and Central Nervous System —Tuberculosis of the meninges and central nervous system figures conspicuously among children in whom the infection proves fatal Deaths at this age are ascribed most often to generalized miliary tuberculosis or tuberculous meningitis In adults meningitis is a relatively infrequent cause of death even among those who have suffered from chronic pulmonary disease Occasionally however it is a terminal event in various forms such as tuberculosis of the genito-urinary organs or bones While leptomeningitis is the commonest manifestation the dura may contain a few hematogenous tubercles or may become involved by extension from an adjacent bony focus such as vertebral caries Limited hematogenous lesions usually cortical may appear also in the cerebrum less often in the cerebellum or spinal cord These may be single or multiple and in rare cases may heal eventually with calcification Such tubercles may be of a chronic granulomatous character gradually increasing in size and producing the clinical manifestations of tumor- the symptoms then depend on the location of the lesion The meninges may become involved secondarily

It is seen therefore that tuberculous meningitis may originate from a tuberculoma previously established in the cortex pia or dura or may develop as part of an acutely disseminated infection from some more remote source Thus it is a common complication of generalized miliary tuberculosis The distribution of the tubercles the perifocal congestion and the fibrinous exudate are characteristically basilar The regions favored are those about the circle of Willis the interpeduncular space the fissures of Sylvius and the optic chiasm Tubercles may be located in and close to the walls of arteries The contiguous brain tissue is edematous or infiltrated for a short distance

The patient may present the clinical picture of generalized miliary tuberculosis for several weeks before meningeal symptoms develop In other cases obvious chronic tuberculous disease may have been present usually in the chest Not infrequently however the patient especially if he is a child previously may have appeared perfectly well For no apparent reason the child becomes listless and irritable The appetite fails and he loses weight If he is too young to describe the headache it may be eloquently indicated by feeling or fumbling his head with his hands and by the sharp so called hydrocephalic cry' or the unmistakable and sustained scream of pain Vomiting is common usually sudden and often projectile sometimes precipitated by a change of position in bed The fever may rise to 103° F or more in the afternoon At first the pulse may be quick but later it becomes slow in proportion to the fever The pupils initially are contracted later dilated As the terminal or paralytic phase follows that of irritation the restlessness night terrors and outcries may give way to stupor whimpering and muttering The patient may be disoriented and wander from his bed There may be clonic contractions of single groups of muscles and not infrequently general convulsions Photophobia is common and there may be strabismus and blepharoptosis Monoplegia or hemiplegia may be observed The initial constipation and urinary retention usually is followed by incontinence

Early in the disease the neck and the muscles of the back and extremities may be sore and stiff The Kernig s sign is usually positive and there may be general hyperreflexia ankle and patellar clonus and a positive Babinski sign Later the muscles may become flaccid and reflexes diminished As the coma deepens the patient may execute athetoid movements Finally he becomes completely motionless the temperature varies widely and irregularly and sweating may be profuse In this unconscious state his eyes half closed and jaw agape he wearily breathes away his final hours

The duration of the disease varies from three to six or eight weeks occasionally

tion at the start may be entirely negative Later, slight tenderness may be elicited on palpation of the kidney or in the upper lumbar region posteriorly Constitutional symptoms if any usually are slight The condition is to be suspected particularly in a patient with pulmonary tuberculosis in the presence of unexplained albuminuria hematuria or pyuria especially the last two even if the quantity of blood or pus is small *Dysuria or cystitis not explained otherwise,* should always be investigated Tubercle bacilli usually are demonstrated on staining the sediment *after centrifugation of from* 500 to 1000 cc of urine or by culture and animal inoculation of this sediment, care being taken to eliminate smegma bacilli Examination may show small or moderate amounts of albumin an abnormal number of erythrocytes and pus cells Pyelography cystoscopy and ureteral catheterization are employed to demonstrate the extent and location of the lesions Nephrectomy is the treatment of choice unless there is more than slight involvement of the opposite kidney If no disease is demonstrated in the opposite kidney this operation leads to recovery in 50 per cent or more of the cases Lesions of the bladder if not extensive show a striking *tendency to heal after the infected* kidney is removed However if the bladder is widely destroyed and symptoms are severe *relief* may be afforded, if at all only by *surgical implantation of the ureters into* the intestine or the skin of the abdomen

Tuberculosis of the Genital Tract — Genital tuberculosis was found in 12 7 per cent of 1143 autopsies on tuberculous subjects by Auerbach at the Seaview Hospital of these 14 4 per cent were in males and 10 4 in females The disease is almost always hematogenous and secondary to preexisting lesions elsewhere in the body *In forty one* cases in females Auerbach found the fallopian tubes involved in 97 5 per cent, the uterus in *58 5 per cent* and the ovaries in 31 7 per cent The cervix is seldom affected the vagina and labia rarely The most com*mon sequel* of salpingitis is localized or diffuse peritonitis Both tubes may be involved but the lesions are usually unilateral There may be few or no localizing symptoms if any, they appear as dull vague pains in the lower abdomen accentuated perhaps during menstruation The menses may be scanty irregular or absent There may be slight or moderate leukorrhea and rarely tubercle bacilli are found in the discharge Pelvic and sometimes abdominal examination may reveal an elongated round mass a few centimeters in diameter in the pelvis The lesions may heal spontaneously if they are not very extensive but if they are chronic surgical resection is favored sometimes to eliminate the focus and prevent extension to the peritoneum

Male genital tuberculosis usually is mani*fested first in the epididymis but pathologic* examinations suggest that the initial focus usually is in the prostate the epididymal lesion being a secondary extension In 105 cases examined at autopsy Auerbach found the prostate involved in 95 2 per cent the seminal vesicles in 61 9 per cent the epididymes in 48.5 per cent and the testes in 20 5 per cent Ljunggren found associated involvement of the kidneys in 50 per cent of sixty cases of tuberculous epididymitis As the lesions progress extension to the opposite epididymis is common The bladder also may be affected secondarily Progressive disease may be followed by the establishment of sinus tracts perforating the scrotum and *allowing the discharge of tuber*culous pus to the outside

The onset of *tuberculous epididymitis* may be insidious with the development of *a nodular or diffuse infiltration* and this may subside and remain latent for a time More commonly the onset is acute with rapid swelling of the epididymis possibly with a serous effusion in the scrotum Later the testis may become swollen painful and even undergo softening Usually the acute inflammation subsides after several weeks leaving behind chronic lesions which may *slowly progress Examination* then may reveal a thickened more or less nodular epididymis and if the testicle participates this may be enlarged to twice or more its natural size The vas may be found thickened and nodular and rectal examination may reveal diffuse or nodular enlargement of the seminal vesicles and prostate *If any* of the lesions have liquefied limited fluctuant areas may be palpable If fistulas *develop tubercle bacilli may* be demonstrated in the discharging pus later they

may appear in the urine. While rest treatment is indicated in these cases, the lesions usually run a chronic course and the prognosis for ultimate healing is not good. Therefore after the acute inflammation has subsided, surgical resection should be considered, especially if the demonstrable lesions are limited and unilateral. Removal of an epididymis, for instance, may prevent further invasion of the seminal tract. The results generally are good.

Tuberculosis of the Meninges and Central Nervous System.—Tuberculosis of the meninges and central nervous system figures conspicuously among children in whom the infection proves fatal. Death at this age is ascribed most often to generalized miliary tuberculosis or tuberculous meningitis. In adults meningitis is a relatively infrequent cause of death even among those who have suffered from chronic pulmonary disease. Occasionally, however, it is a terminal event in various forms such as tuberculosis of the genito-urinary organs or bones. While leptomeningitis is the commonest manifestation, the dura may contain a few hematogenous tubercles or may become involved by extension from an adjacent bony focus, such as vertebral caries. Limited hematogenous lesions, usually cortical, may appear also in the cerebrum, less often in the cerebellum or spinal cord. These may be single or multiple and in rare cases may heal eventually with calcification. Such tubercles may be of a tumor-like granulomatous character, gradually increasing in size and producing the clinical manifestations of tumor, the symptoms then depend on the location of the lesion. The meninges may become involved secondarily.

It is seen, therefore, that tuberculous meningitis may originate from a tuberculoma previously established in the cortex, pia or dura, or may develop as part of an acutely disseminated infection from some more remote source. Thus it is a common complication of generalized miliary tuberculosis. The distribution of the tubercles, the perifocal congestion and the fibrinous exudate are characteristically basilar. The regions favored are those about the circle of Willis, the interpeduncular space, the fissures of Sylvius and the optic chiasm. Tubercles may be located in and close to the walls of arteries. The contiguous brain tissue is edematous or infiltrated for a short distance.

The patient may present the clinical picture of generalized miliary tuberculosis for several weeks before meningeal symptoms develop. In other cases obvious chronic tuberculous disease may have been present, usually in the chest. Not infrequently, however, the patient, especially if he is a child, previously may have appeared perfectly well. For no apparent reason the child becomes listless and irritable. The appetite fails and he loses weight. If he is too young to describe the headache, it may be eloquently indicated by feeling or fumbling his head with his hands and by the sharp so-called "hydrocephalic cry" or the unmistakable and sustained scream of pain. Vomiting is common, usually sudden, and often projectile, sometimes precipitated by a change of position in bed. The fever may rise to 103° F or more in the afternoon. At first the pulse may be quick but later it becomes slow in proportion to the fever. The pupils usually are contracted, later dilated. As the terminal or paralytic phase follows that of irritation, the restlessness, night terrors and outcries may give way to stupor, whimpering and muttering. The patient may be disoriented and wander from his bed. There may be clonic contractions of single groups of muscles and not infrequently general convulsions. Photophobia is common, and there may be strabismus and blepharoptosis. Monoplegia or hemiplegia may be observed. The initial constipation and urinary retention usually is followed by incontinence.

Early in the disease the neck and the muscles of the back and extremities may be sore and stiff. The Kernig's sign is usually positive and there may be general hyperreflexia, ankle and patellar clonus and a positive Babinski sign. Later the muscles may become flaccid and reflexes diminished. As the coma deepens the patient may execute athetoid movements. Finally he becomes completely motionless, the temperature varies widely and irregularly and sweating may be profuse. In this unconscious state, his eyes half closed and jaw agape, he wearily breathes away his final hours.

The duration of the disease varies from three to six or eight weeks, occasionally

deaths in the cases of children have been reported to occur in less than a week after the clinical onset Recovery is very rare

Lumbar puncture yields fluid which is usually clear and under increased pressure occasionally it is slightly turbid As the fluid stands in the tube a thin coagulum develops and tubercle bacilli may be found in this or in the sediment collected after centrifugation Otherwise guinea pig inoculation usually proves positive The number of cells in the fluid usually is 25 or more per cubic millimeter lymphocytes predominating The content of protein is found moderately or markedly increased glucose is decreased

Tuberculosis of Special Structures—The *breast* may be infected hematogenously but more often by extension from an adjacent lesion such as caries of a rib or tuberculous costal chondritis The breast may be diffusely swollen and tender but more commonly localized irregular nodular swellings increasing in size appear in one or more of the segments The conglomerate tubercles usually become caseous leading to the formation of abscesses from which cutaneous fistulas may originate The infection may burrow widely under the pectoral tissues If not too extensive incision of the abscess followed by cauterization with phenol may lead to healing If the glandular tissue is extensively involved mastectomy may be indicated

Tuberculosis of the myocardium while rare may occur through infection extending into it from the epicardium less often from the mediastinal lymph nodes or from the blood stream The lesions may be numerous and isolated or diffuse and caseous Alphonse described tuberculous phlebitis of the myocardial veins An extremely rare lesion is tuberculous endocarditis with valvular vegetations

Tuberculous arteritis of peripheral arteries is also rare sometimes due to the lodgment of infected emboli

Tuberculosis of the hypophysis is very rare Kirschbaum and Levy studied the chronic granulomatous type which may produce the symptoms of diabetes insipidus or of pituitary cachexia (Simmonds disease)

Tuberculosis of the thyroid and of the pancreas is rare and is observed only in generalized hematogenous infection or as an extension from an adjacent lesion Chronic thyroiditis and less often chronic pancreatitis on a tuberculous basis are occasionally reported

Tuberculosis of the adrenals if extensive produces the addisonian syndrome which may be rapidly progressive and fatal In these cases the adrenals are usually found to be caseous A few tubercles may be discovered here in generalized miliary tuberculosis and rarely, old calcifications

Tuberculosis of the Liver—Isolated gray hematogenous tubercles in the capsule or substance of the liver are not uncommon findings at the autopsy of patients who have died of pulmonary tuberculosis and they may be demonstrated in those who have never suffered from this disease In subacute and chronic forms of hematogenous tuberculosis particularly in young children and in Negroes numerous caseous tubercles of various sizes may be found in the liver but chronic destructive tuberculosis of the organ is very uncommon in these cases extensive caseous abscesses may be found Infection of the gallbladder or duct is also infrequent it is usually due to extension from an adjacent focus which may be in the lymph nodes

At Seaview Hospital Stemmerman found *tuberculosis of the bile ducts* in 3 per cent of 1500 autopsies on tuberculous subjects, usually the lesions were miliary or consisted of abscesses 1 to 20 mm in diameter

Tuberculosis of the spleen is a frequent sequel of hematogenous infection A few or many miliary tubercles may be found in the capsule or in the parenchyma or the organ may be enlarged and infiltrated with large caseous conglomerates the latter however is uncommon Encapsulation of caseous tubercles may occur and then these may persist as round nodular calcifications in the living they sometimes may be demonstrated roentgenographically

Tuberculosis of the ear may result occasionally from hematogenous infection but usually is a complication of cavitary pulmonary disease The middle ear may be infected through the eustachian tube usually one ear is involved but both may participate The process is subacute or chronic leading to abscess formation and slow per

foration of the drum after which a chronic fistula often persists Secondary infection then may occur The mastoid may become involved but this is uncommon at least in serious degrees The diagnosis is suggested by gradually increasing painless deafness tinnitus and a feeling of fulness in the ear of a patient with cavitary pulmonary tuberculosis Perforation of the drum is usually painless also Tubercle bacilli to be distinguished from nonpathogenic acid fast organisms said to live in the cerumen may be demonstrated in the discharging pus The inflammation occasionally heals without perforation of the drum leaving permanent partial deafness

The *nose* may become involved in lupus vulgaris the lesions of which may extend to the mucosa Picking of the nose by a tuberculous patient is supposed sometimes to cause infection of the mucosa and development of a chronic perforating septal ulcer *Tuberculosis of the paranasal* sinuses is observed rarely

Tuberculosis of the Larynx, Trachea, and Bronchi—Tuberculous laryngitis is one of the common complications of chronic pulmonary tuberculosis The lesions may be chronic and localized or acute exudative and diffuse The lesion usually appears first at the level of the vocal cords or the arytenoids in the posterior part of larynx There may be a diffuse swelling or tubercle formation in the interarytenoid space at the posterior end of one or both vocal cords or in the region of one or both arytenoid cartilages The inflammation may become almost completely resolved or it may progress with caseation and ulceration The irregular ragged shallow ulcers are found usually in the locations mentioned Later granulations may develop which have a serrated granular or tubercular form If extensive fibrosis may cause slight stenosis of the larynx The early symptoms are huskiness and hoarseness of the voice dryness and very slight soreness of the larynx This may be noticed only on awaking or after talking but usually continues beyond the time expected for simple catarrhal laryngitis Laryngoscopic examination then may show the redness and swelling or tubercle formation in the posterior part of the larynx Later if the lesions progress hoarseness becomes chronic and continuous and the dryness and irritation may cause moderate or severe coughing Pain is not usually a pronounced symptom unless deep invasion of the laryngeal cartilages occurs One of these the epiglottis may become greatly enlarged swollen red and finally deeply ulcerated Such extensive disease results in dysphonia severe dysphagia and salivation and the patient s nutrition may be seriously impaired because of his inability to swallow In treatment the most important principle is vocal rest, the patient being instructed to abstain from using the vocal cords He speaks in a labial whisper or resorts to written communication This together with proper treatment of the pulmonary tuberculosis usually results in healing during the early stages Later treatment with a specially constructed actual cautery may be necessary and very helpful Severe symptoms may be alleviated by the use of anesthetic sprays topically, or alcohol injection of the superior laryngeal nerve In any case of tuberculosis of the larynx the lungs should be examined since they are almost invariably involved

The bronchi leading from a tuberculous pulmonary cavity usually are invaded and in some cases lesions in the larger bronchi or trachea assume important clinical significance Shallow lenticular ulcers of the mucosa are not uncommon and more pronounced lesions develop occasionally in patients especially women with long-standing pulmonary disease The bronchial wall may be attacked also by lesions in contiguous lymph nodes The bronchial lesions consist of ulcers which are superficial or penetrate to or through the cartilage or of granulomatous and fibrous formations which may partially occlude the lumen Healing in the early stages leaves little or no scar but more advanced lesions may be followed by extensive organization of the bronchial and peribronchial tissues with contraction and cicatricial stenosis Occasionally a bronchus is completely occluded The affected bronchus may fail in its function as a drainage tube and in this event the related segment of the lung becomes involved with secondary pyogenic infection resulting in bronchopneumonia which may be suppurative and associated with bronchiectasis The diagnosis depends on eliciting the history of symptoms

of bronchial stenosis or ulceration such as persistent wheezing and the auscultation of rhonchi confined mostly to one side of the chest or to one lobe Similarly the symptoms and signs of associated suppurative pneumonia may lead to the diagnosis Roentgenographic evidence of obstructive emphysema or of diffuse pneumonia is suggestive Bronchoscopy discloses the ulcerous granulating or stenotic lesions which in some cases may be treated by topical applications Artificial pneumothorax to collapse the lung early may prevent the development of suppurative pneumonia and aid the healing of the bronchial lesion by stopping the flow of pus from a tuberculous cavity and by reducing motion of the bronchus Catheter drainage of occluded cavities thoracoplasty and pneumonectomy are now used with some success in the more serious cases

Tuberculosis of the Alimentary Tract —*Tuberculosis of the mouth* appears most often as ulceration of the tongue which becomes infected as a rule by extension from a laryngeal lesion or through an abrasion caused by biting or other trauma from the teeth The lesion is situated most often on the margin but may involve the dorsum especially at the base The ulcer at first is superficial but progressive infiltration and caseation often follow with extensive destruction of the muscle The chronic ulcers are often fissured and yellow caseous or red granulating tubercles may be found in their depths The indurated base is usually palpable The ulcer is usually single but others may appear The diagnosis depends on the finding of such a lesion in a tuberculous patient and may be confirmed by demonstrating the organisms in curettings from the ulcer Biopsy is to be avoided unless necessary Treatment consists of cauterization with the actual cautery, rarely the ulcer bearing area may be resected with success Local heliotherapy may be helpful

Tuberculosis of the lip is found usually under similar circumstances the lesion appearing much the same as that of the tongue An ulcer at the corner of the mouth may be fissure like and erode deeply

Tuberculosis of the salivary glands is rare possibly because of the alkaline reaction of the tissue (Vivoli *et al*) Sarnia reported a case of tuberculosis of the parotid gland which could not be distinguished clinically from malignancy mixed tumor or other types of inflammation

Tuberculosis of the pharynx is found most often in association with lesions of the tonsil Infection of the latter may be due to surface contamination or to hematogenous dissemination from a distant focus Upon examining 2000 pairs of tonsils removed surgically Long Seibert and Gonzales found that the incidence of tuberculous lesions depends roughly on the prevalence of tuberculosis in the community, it was 6.5 per cent in specimens from American Indians 2.5 and 0.25 per cent in those from Puerto Ricans and Philadelphians respectively The lesions are usually deep and focal In cases recognized clinically the tonsil is slightly or moderately enlarged and may show yellow or whitish caseous areas beneath the shiny mucosa later these break down leaving *ulcers of a grayish yellow ragged character* One or both tonsils may participate When the pharynx becomes infected secondarily the fauces soft palate and uvula become thickly seeded with granular miliary tubercles some of which have a minute yellowish center These coalesce break down and form fissured ulcers and the tissues may be slowly destroyed The pain is severe salivation profuse and dysphagia marked Such extensive disease is usually fatal Limited ulcers may appear on the posterior pharyngeal wall and these sometimes may be treated successfully with heliotherapy or direct cauterization Pharyngeal lesions may be associated with tuberculosis of the larynx

Tuberculosis of the esophagus is relatively rare The upper end may be involved by direct extension from severe tuberculosis of the larynx Tuberculous lymph nodes of the mediastinum after caseation may perforate the esophagus discharging their contents or the periadenitis may involve the esophagus without perforation In either event the cicatricial contraction may result in diverticula of the esophagus *Tuberculosis of the stomach* is reported in a few cases of pulmonary disease at autopsy (up to 2 per cent) The lesions usually extend to the stomach from a contiguous structure but they may be hematogenous or result from contamination by swallowed discharges from the lungs The gastric wall may be infiltrated

or there may be an ulcer, usually near the pylorus which grossly resembles carcinoma

The *intestine* is most frequently involved the commonest site being the lower ileum and cecum The mechanism of infection is principally from surface contamination with swallowed tubercle bacilli in patients with pulmonary tuberculosis (up to 70 per cent at autopsy) Much less often infection may be caused by primary invasion (*e g* contaminated milk) hematogenous dissemination or by extension from tuberculous peritonitis Infiltration of the intestinal mucosa and lymphoid tissue usually is followed soon by superficial ulceration the ulcers may extend rapidly or become localized and chronic with an organizing granulating base and overlying fibrinous or fibrous peritonitis Sometimes as in the cecum the proliferative granulomatous changes become very protracted leading to great thickening of the wall fibrous peritonitis and narrowing of the intestinal lumen the whole forming a tumorous mass Acutely progressive ulceration may involve several feet of the intestinal mucosa enclosing small islands of intact tissue Perforation of the wall by the ulcer is very infrequent Small ulcers may heal and the mucosa apparently regenerate

The initial symptoms are indefinite and considerable ulceration may be found in patients who have never had abdominal complaints At first there is slight to moderate loss of weight vague indigestion loss of appetite irritability and secondary anemia Local symptoms may appear early or late as a change in the usual rhythm of the stools A short attack of mild diarrhea may be followed by constipation and after an apparently normal interval this may recur After many weeks or months diarrhea may become frequent and finally the patient will have ten to twelve evacuations during the day and night the diarrhea being watery and foul seldom bloody The diarrheal attacks are associated often with colicky pains in the lower half of the abdomen aggravated perhaps by taking certain foods such as raw fruit The patient may become anemic and emaciated Physical examination usually reveals no palpable masses and frequently no tenderness although the patient may complain of a little soreness on deep palpation especially in the right lower quadrant In certain mild chronic cases the recurrent pain simulates simple chronic appendicitis, in fact, the appendix may be involved in the tuberculous process Sometimes this is not suspected until the lesions are discovered on routine histologic examination of the resected appendix In cases of tuberculous enterocolitis roentgenographic examination after a barium meal or enema may reveal spasticity filling defects and hypermotility of the lower ileum cecum and ascending colon Treatment consists first in proper general management and prescribed rest since these patients almost always have chronic pulmonary tuberculosis The most important adjuvant is regulation of the diet which should be bland raw fruits fruit juices and fat may have to be reduced or eliminated temporarily and vitamins given parenterally Medication to relieve pain and lessen the intestinal spasm may be indicated in the form of powdered opium or paregoric bismuth subnitrate or bismuth subgallate by mouth or calcium gluconate intravenously General heliotherapy in graduated doses may be of value after the acute symptoms have been controlled As a prophylactic against intestinal complications in patients with pulmonary disease McConkey has reported considerable success with the routine use of a cocktail of tomato juice and cod liver oil

Tuberculous ischiorectal abscess or *perianal abscess* and fistula is due usually to infection in a similar way and starts with a localized painful perianal swelling which becomes acutely tender within a few days or several weeks If not incised this may perforate the skin to the exterior less often the wall of the rectum with the discharge of nonodorous pus in which tubercle bacilli may be demonstrated The resulting fistula is apt to be chronic and later to require surgical treatment

J Burns Amberson Jr

PREVENTION OF TUBERCULOSIS

The observations that relative immunity may be conferred upon animals and that naturally acquired and limited tuberculous lesions have a similar effect in man have stimulated many attempts to develop means

of prophylactic vaccination and passive transference of immune bodies Killed devitalized and attenuated bacilli have been tried as vaccines administered by various routes as have fractions and products of the bacilli and of the lesions caused by them It has been shown that relative immunity may develop, usually in slight degree after the administration of living or dead virulent or attenuated organisms The duration of this may be a relatively few months, or some years Absolute protection against subsequent virulent infection has never been proved and no plan has justified itself thus far for universal application One of the better known vaccines, B C G an attenuated living strain of the bovine type of bacillus prepared by Calmette and Guerin, appears to have an immunizing capacity, and the degree of this is still under study Some believe that a return of virulence to such strains is not an impossibility

Measures which are assuredly effective for prevention include the following

Elimination of tuberculous animals and pasteurization of milk

Improvement of living conditions and education in personal hygiene

Adequate medical examinations to detect lesions in their incipiency usually in the preclinical phase

Sufficient and proper treatment of the early case to prevent excavation of the lesion and infection of 'contacts

Isolation of the infectious case

Rehabilitation of patients with arrested disease to prevent relapse

FRIEDLANDER S BACILLUS INFECTIONS

The Organisms —Friedlander s bacillus (synonyms *Bacillus mucosus capsulatus B friedlanderi B pneumoniae Pneumobacillus Klebsiella pneumoniae Encapsulatus mucosus*) is an encapsulated short plump nonmotile gram negative rod with rounded end which grows to form mucoid gelatinous colonies on agar and a slimy surface pellicle in broth Three distinct serologic types A B and C are distinguishable by agglutination mouse protection precipitin tests and capsular swelling in specific immune serums and the two latter tests may be used for identifying the types directly from sputum exudates or cultures Other strains are classified as type X' although further specific types (D and E Cooper) have been noted Type B cross reacts in all tests with Type II pneumococcus especially with horse anti sera Type specificity resides in the capsular polysaccharide and this may be identified in cultures and in blood and urine of infected patients or animals While Friedlander s bacilli are readily distinguishable as a rule morphologically and culturally, biologic tests are unsatisfactory for absolutely differentiating them from closely related or

ganisms of the *rhinoscleroma* or *lactis aerogenes* groups so that they are often referred to as the Friedländer group of bacilli

Occurrence and Pathogenicity.—Friedlander s bacilli occur in the respiratory passages of from 2 to 25 per cent of normal persons in the normal intestinal tract even in infants and in the respiratory tract of mice guinea pigs and rabbits They have been found in soil dust, air and water They are pathogenic for man producing characteristic acute and chronic pulmonary infections and also suppurative infections in the upper respiratory passages in the intestinal biliary genital and urinary tracts and in serous cavities and meninges and give rise to septicemia and pyemia They produce septicemia and widespread lesions when injected into mice guinea pigs and rabbits

History —The organism was discovered by Friedlander in 1882 It was first described as a coccus and as the cause of pneumonia. This gave rise to considerable confusion and to a bitter controversy especially with Fraenkel The controversy was essentially resolved in 1886 by Weichselbaum who came around to the view now generally held namely that the pneumococcus is the chief etiologic agent of pneumonia and that Friedlander's bacillus may be the cause in a small percentage of cases

MAXWELL FINLAND

FRIEDLANDER S BACILLUS PNEUMONIA

Definition —Friedlander s bacillus pneumonia is a specific acute infectious disease caused by Friedländer's bacillus and characterized by massive mucoid inflammatory exudate of lobar or confluent lobular distribution in one or more lobes of the lung with a tendency to necrosis and abscess formation

Incidence and Distribution —Friedländer s pneumonia constitutes from 0 6 to 13 per cent of all cases of pneumonia in different series averaging 1 1 per cent in over 17 000 cases (Julianelle) It has been encountered in most parts of the world and in all seasons The disease is usually sporadic but contact cases and epidemics have occurred

Etiology —The etiologic relationship of the Friedlander s bacillus to pneumonia has now been authentically established in a large number of cases The organism has been found in pure culture during the first days of the disease in sputum lung and pleural fluids and in blood cultures, and has been obtained in direct smears and cultures from the blood and lungs at autopsy in rapidly fatal cases The pneumonias are caused predominantly by type A strains which are found in about two thirds of the cases Type B is next in frequency

Predisposing Factors —Pneumonia due to Friedlander s bacillus has its greatest incidence between the ages of forty and sixty years and is rarely encountered in infants and young children Chronic alcoholism malnutrition and general debility are encountered frequently in these cases Antecedent simple upper respiratory infections are relatively infrequent although occasional cases complicating influenza were encountered during the 1918 pandemic The disease may occur as a secondary infection following pneumonia due to other organisms particularly pneumococci or contrariwise it may be followed by infections with other organisms

Morbid Anatomy —The involved lung is heavy voluminous and noncrepitant with massive consolidation (lobar or confluent lobular) of one or more entire lobes Plaques of fibrin are found on the pleural surfaces The cut section of the affected areas usually has a smooth but mottled gray red or red brown surface from which thick stringy mucinous exudate often oozes as if under pressure The underlying lung often reveals soft areas in which alveoli appear liquefied and replaced by the mucinous exudate In older lesions there may be gray green purulent exudate with large areas of abscess formation Histologically the outsanding features are the necrosis of alveolar tissue the enormous numbers of encapsulated bacilli seen free or intracellular and the inflammatory exudate consisting of polynuclear large mononuclear (alveolar epithelial cells or monocytes) and red blood cells in varying proportions with only a small amount of fibrin

Symptoms and Course —In the majority of cases the onset is acute and begins like pneumococcus pneumonia with chill pleuritic pain cough and bloody sputum Profound prostration sets in early and delirium and distention are common Dyspnea and cyanosis also occur early and may be very

intense Free hemoptysis occurs in the majority of cases Sputum is usually copious but is often raised with difficulty because of its mucoid and sticky character, it may appear rusty but is more often brick red or bloody and gelatinous resembling currant jelly *Organisms are abundant in smears of* such sputum Vomiting and diarrhea are frequent and jaundice is present in many of the severe cases Occasionally there is hematemesis or melena Erythemas sometimes scarlatiniform occur and patients with bacteremia may have petechiae Herpes rarely occurs

Signs of consolidation may be made out early, but more often the classical signs are absent and there may be only dulness and muffled breath sounds even when massive density is visible in the roentgenogram This is presumably due to plugging of bronchi with viscid exudate Moist rales may be heard over some areas of the lung Involvement of the upper lobes or of multiple lobes is more frequent than in the pneumococcus pneumonias The fever is variable, it may be sustained or irregular, but usually ranges lower than in cases due to pneumococci

The disease may run a fulminating course ending fatally in twenty four to thirty six hours The average duration in Bullowa s cases was about five and a half days Death is usually associated with either peripheral vascular collapse pulmonary edema or extreme respiratory distress without pulmonary edema Recovery is sometimes by crisis but more often it is by lysis and then may frequently be followed by the chronic type of pulmonary infections to be described later

Laboratory Findings —The chief distinctive finding of interest is the large number of the characteristic bacilli seen in smears of the sputum Agar cultures made of the sputum directly yield the characteristic mucoid colonies usually in pure culture Blood cultures yield the same organisms in more than half of the cases and the organisms may be obtained almost regularly in pure culture by lung puncture or from pleural exudates even when the blood culture is sterile The bacilli may be typed directly from sputum exudate lung juice or blood culture growth by the capsular swelling with homologous rabbit antiserum as in the case of pneumococci The type-specific capsular polysaccharide may often be demonstrated in the patient s serum and in the urine during the acute disease, and it is also found in exudates Specific agglutinins may appear after the fifth day Total leukocyte counts below 6 000 occur in more than one third of the cases In other cases there is a moderate leukocytosis, with total counts reaching 25 000 or 30 000 in the presence of purulent complications

Roentgenograms usually show marked density developing early Areas of rarefaction may appear later, indicating abscess and cavity formation which in patients who survive long enough then shows evidence of healing and fibrosis

Diagnosis —Friedlander's bacillus pneumonia is suspected in any case of acute pneumonia with severe prostration occurring early, especially if there is bloody gelatinous sputum The diagnosis is based on demonstrating the characteristic encapsulated bacilli in smears and cultures of sputum as the only or predominant organism They may be typed directly by the Neufeld method The disease in some of its stages may simulate acute pneumonias due to other organisms particularly the pneumococcus pulmonary tuberculosis influenza ' pneumonia acute pulmonary infarction and bronchiectasis

Prognosis —The mortality in sporadic acute cases is high averaging about 80 per cent, regardless of whether or not bacteremia is demonstrated The mortality figures however are complicated because of the exclusion by some authors of some of the cases having a more chronic course in which the mortality is lower even when bacteremia occurs early

Treatment —The general and symptomatic treatment is the same as for severe cases of lobar pneumonia due to the pneumococcus There is some suggestive evidence of benefit from early and adequate treatment in type A cases with the homologous antiserum, but the results on the whole have been disappointing Sulfonamides have been widely used but the results are as yet difficult to assess Reports are available of recoveries with sulfapyridine sulfathiazole and sulfadiazine The latter appears to be the most promising of this group In view of the severity and rapid course it is advisable

to begin treatment with an initial intravenous dose of 0 1 Gm per kilogram of sodium sulfadiazine given as a 5 per cent solution in distilled water or as 0.5 or 1 0 per cent solution in physiologic saline Subsequent doses usually of 1 Gm each are given orally at 4 hour intervals and then adjusted so as to maintain high blood levels (about 15 mg per 100 cc), and adequate fluids (3 000 cc or more) given to permit an output of 1,500 cc or more per day Treatment in full doses for ten days or longer may be necessary

Complications —The commonest complication is delayed resolution with abscess formation and fibrosis of the lung (see below) Pleurisy is very frequent Empyema pericarditis meningitis nonsuppurative arthritis and superinfections with other organisms notably pneumococci and hemolytic streptococci have been noted Empyema and lung abscess which doesn t drain properly may require surgical intervention but this should be avoided in the latter instance if possible because a chronic sinusitis may result Section or crushing of the phrenic nerve may be resorted to in such cases

MAXWELL FINLAND

CHRONIC FRIEDLANDER S BACILLUS INFECTIONS OF THE LUNGS

Definition —Subacute or chronic infections of the lung caused by Friedländer s bacillus with a protracted and relatively benign course and expectoration of purulent nonputrid and sometimes bloody sputum Characteristically they are accompanied by abscess formation bronchiectasis and pulmonary fibrosis and exhibit a tendency to exacerbations of acute pneumonia

Occurrence, Etiology and Pathogenesis —The exact incidence of these chronic forms is difficult to establish but they are much less frequent than the acute Friedländer pneumonias Probably many cases go unrecognized and are included as tuberculosis or as other chronic pulmonary infections The relation of the Friedlander s bacillus to the disease is based upon finding the organism in large numbers and often in pure culture in sputum in abscess or pleural fluid or in blood cultures during acute phases Other organisms are also found in varying numbers in the latter stages

Morbid Anatomy.—Grossly the lungs present a picture of confluent bronchopneumonia with fibrosis bronchiectasis and abscess formation Since the upper lobes are usually involved, the gross picture resembles that of pulmonary tuberculosis with cavitation but there is no caseation The walls of the cavities consist of bundles of collagen fibers bearing connective tissue cells without the remains of alveolar walls Bronchi showing bronchiectatic changes often blend with foci of acute inflammation and with abscesses

Symptoms and Course —The disease usually begins as an acute Friedländer s pneumonia with slow lysis over a period of weeks, during which abscess formation and fibrosis of the lung occur In some cases there is a milder course from the start with low grade persistent fever cough with copious purulent sputum loss of weight and recurrent pleurisy The sputum is not foul (unless there is a mixed infection) and intermittently becomes blood streaked brick red or grossly bloody The disease may go on for several weeks and end in complete symptomatic recovery with apparent clearing of the lesions by x ray, or it may persist for many months or years In most instances there is chronic abscess formation and bronchiectasis with fibrosis which tend to reproduce the disease and give rise to relapses and frequent hemoptysis particularly after acute respiratory infections In more than three-fourths of the cases one or both upper lobes are involved so that the entire clinical and x ray picture closely resembles that of pulmonary tuberculosis with cavitation

Laboratory Findings —The typical encapsulated bacilli are always present in large numbers Secondary organisms including pneumococci staphylococci influenza bacilli and other common mouth inhabitants may also be abundant Bacteremia is less common in these cases but positive blood cultures have been obtained during the original acute pneumonia and during exacerbations Specific antibodies may be demonstrated early and persist for a few weeks Low grade leukocytosis is the rule except during acute phases when there may be a leukopenia X rays show thin walled cavities with or without fluid and later there

is fibrosis and retraction of the upper lobes, simulating tuberculosis

Diagnosis—In cases seen during the acute phase, the diagnosis is made when there is slow lysis and evidence of abscess formation with copious sputum The disease may be simulated by pulmonary tuberculosis with cavitation Many cases with the latter diagnosis in whom tubercle bacilli are not found are shown to have chronic Friedlander's infections The diagnosis depends on repeatedly demonstrating the characteristic encapsulated bacilli as the only or predominant organism in smears and cultures Staphylococcal pneumonias bronchomycoses lung abscess bronchiectasis and tumors of the lung must be considered in the differential diagnosis

Prognosis.—The mortality is said to be about 25 per cent Death may occur in the original attack after a slowly progressive illness of several weeks or months, or it may occur during an acute exacerbation of pneumonia with the same or other organisms, or as a result of complications such as pericarditis meningitis or following operation for empyema or lung abscesses Some patients apparently recover completely while most of the others continue to have signs and symptoms for as long as 20 years or more

Complications—Recurrent pleurisy is frequent Empyema usually encapsulated with thick mucoid pus may occur with or without relation to abscess formation in the lung Serous effusions are encountered which may be sterile or infected and may occur in patients who have purulent empyema elsewhere Recurrences of acute pneumonia and hemoptyses are the rule Axillary thrombophlebitis with acute arthritis has been encountered Pericarditis and meningitis may occur as terminal events

Treatment—On the whole the treatment is disappointing Cases are recorded in which the use of sulfonamide drugs during a relapse resulted in apparent clearing up of the infected focus but the results on the whole are unsatisfactory Empyema usually necessitates rib resection and this may also be necessary for large pulmonary abscesses which fail to drain Conservative treatment is recommended for abscesses in general in the hope that they will eventually drain into a bronchus

MAXWELL FINLAND

FRIEDLANDER'S BACILLUS SEPSIS

Definition—Local or generalized infections caused by the Friedlander's bacillus frequently accompanied by bacteremia and associated with localized purulent infections in one or more organs

Septicemia with this organism is relatively uncommon and is less frequent than with the streptococcus, staphylococcus colon bacillus meningococcus or pneumococcus Several types are described (1) a pure septicemic type which has an acute and rapidly fatal course, (2) a pyemic type with multiple abscesses in many organs, (3) a septicemia with symptoms referable predominantly to one organ, and (4) one which is secondary to infection with other organisms

Portal of Entry—The organisms may gain access to the blood stream from any of the following foci the middle ear the lungs particularly where there is thrombophlebitis of the pulmonary vein, the intestinal tract which is common in infants, the liver especially when there is thrombophlebitis of the hepatic or portal vein the urinary tract the genital tract notably the prostate in males the adnexa or the puerperal uterus in females A large proportion of the cases are so called cryptogenic and the original focus cannot be determined even at autopsy

Etiology—Not all of the reported cases have sufficient information to identify the organism with certainty Little is known also concerning the type distribution in these cases The organism is recovered in pure culture from the blood and from foci of suppuration, and frequently from the urine

Occurrence and Predisposing Factors—Many of the cases occur in infants children and young adults of both sexes differing in these respects from the pneumonias Alcoholism cirrhosis of the liver and diabetes are particularly frequent in the adult cases

Morbid Anatomy—The dominant feature is the finding of metastatic abscesses in the liver lungs and kidneys Only those in the lungs are characteristic The pus in the abscesses is usually mucoid and tenacious and the characteristic organisms are readily found in large numbers in smears and are usually in pure culture Ulcerative endocarditis meningitis and involvement of serous cavities are sometimes encountered

Symptoms and Course —The onset may be abrupt with severe chills or it may be insidious with high continuous or intermittent fever and general malaise with or without chills Vomiting and diarrhea are common Rashes occur and may be either scarlatiniform maculopapular or petechial in character There is an acute fulminating type described (Blumer and Laird) with a hemorrhagic septicemia in which intestinal symptoms predominate and in which changes in the intestine similar to those of typhoid fever are found at autopsy In some cases particularly in adolescents the course may simulate typhoid fever in every respect including the leukopenia In others the picture is dominated by some local lesion such as abscesses of the kidney, lungs prostate or liver or by a cholecystitis with ascending infection or there may be perforation of the intestine with peritonitis In the cases with liver abscesses jaundice may be prominent The disease may be of short duration or last for several weeks Meningitis or endocarditis may occur terminally

Diagnosis —This depends on finding the Friedlander s bacillus in blood cultures or on demonstrating the organisms in characteristic pus from metastatic lesions

Prognosis —The mortality is high but except in cases with pyemia recoveries are recorded in all types of cases including some which have shown a persistent bacteremia for some time The prognosis is particularly favorable in cases in which there is a predominant focus such as the prostate which is accessible to surgical drainage

Treatment —Sulfonamide drugs particularly sulfadiazine are indicated in full doses and an effort should be made to maintain high blood concentrations (about 15 mg per cent) for two or more weeks Specific serotherapy may also be used as an adjunct Accessible foci should be drained surgically

Maxwell Finland

FOCAL INFECTIONS DUE TO FRIEDLANDER S BACILLUS

Occurrence —According to some writers notably Baehr *et al* these represent the bulk of infections with the Friedlander s bacillus and they assign only a secondary role to the pulmonary infections They consider the most common infections caused by the Friedlander's bacillus to be in the abdomen and to originate in the intestinal tract These include appendiceal and subphrenic abscesses and peritonitis In most of the cases the organisms are obtained in pure culture but in a large proportion they are found together with the colon bacillus An epidemic form of diarrhea in children has been ascribed to the Friedlander's bacillus The urinary tract is the next most frequent site of infection Here and in infections of the gallbladder and bile ducts associated defects particularly those causing obstruction are present in almost all cases in which suppuration occurs Positive cultures may be obtained from the duodenal bile in some of the cases of biliary tract infections Occasional cases have a course simulating catarrhal jaundice Prostatitis salpingitis infections of the skin and of the uterus and vagina have all been encountered Suppurative arthritis is usually a metastatic lesion and ulcerative endocarditis occurs in cases with associated bacteremia Meningitis may occur following sinusitis otitis media or following trauma

Course and Treatment —The course depends on the site of the lesion Transient bacteremia may occur in any of these cases In acute severe cases especially those with bacteremia intensive chemotherapy supplemented by specific serum should be used Surgical drainage is indicated whenever collections of pus become accessible Urinary tract infections are amenable to treatment with sulfathiazole or sulfadiazine Where obstructive lesions of the intestinal biliary or urinary tract are present the obstruction must be relieved if possible in order to bring about a cure of the infection

Definition—Local or generalized infections caused by the Friedlander's bacillus, frequently accompanied by bacteremia and associated with localized purulent infections in one or more organs

Septicemia with this organism is relatively uncommon and is less frequent than with the streptococcus staphylococcus colon bacillus meningococcus or pneumococcus Several types are described (1) a pure septicemic type which has an acute and rapidly fatal course, (2) a pyemic type with multiple abscesses in many organs (3) a septicemia with symptoms referable predominantly to one organ, and (4) one which is secondary to infection with other organisms

Portal of Entry—The organisms may gain access to the blood stream from any of the following foci the middle ear the lungs particularly where there is thrombophlebitis of the pulmonary vein the intestinal tract, which is common in infants the liver, especially when there is thrombophlebitis of the hepatic or portal vein the urinary tract the genital tract, notably the prostate in males the adnexa or the puerperal uterus in females A large proportion of the cases are so called cryptogenic and the original focus cannot be determined even at autopsy

Etiology—Not all of the reported cases have sufficient information to identify the organism with certainty Little is known also concerning the type distribution in these cases The organism is recovered in pure culture from the blood and from foci of suppuration and frequently from the urine

Occurrence and Predisposing Factors—Many of the cases occur in infants, children and young adults of both sexes differing in these respects from the pneumonias Alcoholism cirrhosis of the liver and diabetes are particularly frequent in the adult cases

Morbid Anatomy—The dominant feature is the finding of metastatic abscesses in the liver lungs and kidneys Only those in the lungs are characteristic The pus in the abscesses is usually mucoid and tenacious and the characteristic organisms are readily found in large numbers in smears and are usually in pure culture Ulcerative endocarditis meningitis and involvement of serous cavities are sometimes encountered

sinuses and in the discharge are found either the characteristic sulfur granule with its clubbed ends or small tangled masses of gram positive branching filaments which may or may not be partially acid fast

History —In 1877 Bollinger found the ray fungus in a disease of cattle known as "lumpy jaw" it was named *Actinomyces bovis* by Harz. J Israel, in 1878 discovered the disease in man and pointed out the identity of the two infections Lord in 1910 demonstrated that *Actinomyces* pathogenic for guinea-pigs could be found in the gums and tonsils of apparently normal individuals In 1914 Schottmüller isolated a streptothrix from the lesions of a patient with rat bite fever The work of Dawson in 1932 indicates that this type of rat bite fever is caused by the same organism that produces erythema arthriticum epidemicum (Haverhill fever) It is generally related to the *Actinomyces* and should be called *Actinomyces moniliformis* or *Actinomyces haverhilli*.

Etiology —Actinomycosis is widely disseminated and is the most common of the highly fatal mycoses The disease occurs most frequently in males

Bacteriology —The organism occurs in pus or tissues as lobulated or spherical granules which vary in size from very minute particles to forms about 1 mm in diameter Pure cultures are readily obtained from material aspirated from unopened abscesses but isolation is very difficult from draining sinuses because of the overgrowth from contaminating bacteria *Actinomyces bovis* is anaerobic and grows best at 37° C in glucose agar in a zone 5 to 10 mm below the surface

Actinomyces asteroides (*Streptothrix asteroides* atypical *Actinomyces Cladothrix* or *Nocardia*) is aerobic and grows on ordinary laboratory media at room and incubator temperatures The colonies are chromogenic and have the consistency of tubercle bacilli The granules are less compact than those of the true sulfur granule of *Actinomyces bovis* The filaments are gram positive frequently show branching and are more or less acid fast True club formation is absent but club shaped swelling of the terminal portion of the filaments may be observed Pure cultures of some strains produce a rapidly fatal disease in guinea pigs in ten to twenty days

Immunology —Not much is known about the serologic reactions of patients with actinomycosis

Pathology.—Actinomycosis may develop in any part of the body A granulomatous lesion is produced which is surrounded and intersected by new connective tissue Multiple interconnected abscesses form which, on rupturing to the surface produce multiple sinuses The local lesions spread by direct extension through the connective tissue rather than by way of the lymphatics although metastatic lesions appear in various parts of the body as a result of showers of infected emboli Colonies of the invading organisms are surrounded by mononuclear cells with an occasional giant cell and numerous polymorphonuclear leukocytes are found in the necrotic areas and in the walls of the sinuses

Symptoms —The clinical symptoms vary somewhat depending upon the part of the body involved

Cervicofacial actinomycosis accounts for more than 50 per cent of all instances of the disease Infection takes place through the mucous membranes of the gums mouth pharynx or larynx The whole infected area becomes indurated or wooden in consistency and this extends beyond the apparent area of inflammation The overlying skin has a dark red or purplish color and a lumpy uneven surface As the infection spreads to the surface multiple sinus tracts appear With internal extension the bones of the skull and even the meninges and brain may be involved Trismus develops when the muscles of mastication are involved and dyspnea when there is pressure on the larynx The lymph nodes of the neck usually are not involved Pain is not a prominent feature and the patient s general health is not much affected so long as the disease remains localized in the area of the face and neck

Thoracic actinomycosis occurs in about 15 per cent of the cases and produces cough sputum increasing dyspnea slight fever loss of weight and strength night sweats pallor and emaciation The sputum contains blood in about half the cases and sometimes a fatal hemoptysis occurs Pleural pain is common and effusions not infrequent After the disease has reached the pleura it usually involves the thoracic wall extends through the subcutaneous tissues and produces localized areas of induration with suppurating

HAVERHILL FEVER

(*Erythema Arthriticum Epidemicum*)

Haverhill fever was first recognized as a clinical entity in this country in 1926 when Place Sutton and Willner reported an epidemic of 86 cases which occurred in Haverhill Massachusetts Eight years later Place and Sutton summarized the symptomatology of the disease as follows (1) An abrupt onset with chills fever malaise vomiting and headache (2) An early eruption, rubelliform or morbilliform occurring first and often only on the extremities especially about the ankles and wrists and tending to become hemorrhagic (3) A multiple arthritis of varying but often of severe and crippling degree (4) A fever with abrupt rise and remission in from two to five days, after a few days of relative freedom from symptoms a recurrence at which time the arthritic manifestations appear (5) A strong tendency to occur in epidemic form

Etiology —Haverhill fever is caused by an organism which was named by Parker and Hudson *Haverhillia multiformis* after studying cultures from twelve cases of the Haverhill epidemic It is recoverable from the joints of patients with the disease There is still confusion as to whether this organism should be classified as an actinomyces or as a member of the family *Bacteriaceae* More recently there has been a tendency to call the organism *Streptobacillus moniliformis* Serum from patients with Haverhill fever show agglutinins for the organism in high dilutions

Differential Diagnosis —Haverhill fever should be differentiated from rat bite fever whether due to *Spirillum minus* (Sodoku) or *Streptobacillus moniliformis* (bacteriologically indistinguishable from the etiologic agent of Haverhill fever) Rat bite fever, as so far reported always follows the bite of a rat or similar animal rarely produces any arthritis and has no tendency to occur in epidemic form While Haverhill fever has been known to follow the bite of a rat, it generally results from drinking contaminated milk

Haverhill fever must also be differentiated from rheumatoid arthritis erythema multiforme, influenza, and undulant fever

Prognosis —Only a few deaths have been reported The patients usually recover in from two weeks to two months

Treatment —Treatment is largely symptomatic Arsenicals such as neoarsphenamine have been tried with questionable success in a few cases

THE MYCOSES

ACTINOMYCOSIS

Definition —Actinomycosis is a chronic granulomatous infection caused by several species of the genus *Actinomyces* The disease is characterized by the development of numerous abscesses which break down and develop multiple sinuses In the walls of the

BLASTOMYCOSIS

Definition.—Blastomycosis is a chronic granulomatous disease which may be confined either to the skin or lungs or disseminated throughout the body

History —The disease was first described by Gilchrist in 1894 and by Gilchrist and Stokes in 1896 It is found frequently throughout the western hemisphere but only sporadically in Europe and is usually called American blastomycosis or Gilchrist s disease and should not be confused with European "blastomycosis which is caused by *Cryptococcus hominis* (*Torula histolytica*)

Etiology—In previous editions it was stated that blastomycosis was most prevalent in the Chicago area Now it is known to be equally common in Louisiana Tennessee North Carolina and other parts of the country The disease is nine times as frequent in males as females

Bacteriology—The morphologic studies of Conant and the serologic investigations of Martin show that all strains of *Blastomyces dermatitidis* are morphologically and antigenically identical Sputum pus or biopsy material should be streaked heavily on Sabouraud s slants and on blood agar plates The slants are kept at room temperature but the blood agar plates should be incubated at 37° C The primary growth may be slow and cultures should be watched for two or three weeks On blood agar the colonies are small waxy and wrinkled and when emulsified in water and examined fresh under the microscope show typical budding double contoured yeast like forms (7–10 microns) identical in appearance with those found in the lesions

Immunology—Many patients develop a sensitivity to the products of *B dermatitidis* and give a skin test analogous to the tuberculin reaction Martin has found that patients with extensive involvement usually show a positive complement fixation when the whole yeast organism or certain of its extracts are used as the antigen The test is negative when the lesions are small or well localized and becomes negative in the systemic cases after recovery

Pathology—The primary skin lesions may be of a superficial verrucous type with little ulceration or gummatous like with open craters The multiple subcutaneous abscesses found in the systemic type of blastomycosis are analogous to cold abscesses in tuberculosis When the disease spreads from the skin bones or other organs to the lungs it produces the appearance in the x ray, and at necropsy, of a miliary hematogenous tuberculosis

Primary infection in the lungs often is localized to one or more lobes and may be *confused with atypical pneumonia tuberculosis* or lung abscess The microscopic picture simulates that of tuberculosis but there are usually many small microscopic abscesses with a polymorphonuclear reaction scattered throughout the lesions The characteristic budding organisms are found in the giant cells in the granulation tissue between the cells and about the edges of the necrotic areas

Symptoms—*Cutaneous blastomycosis* occurs most frequently on the face neck or extremities The primary lesion usually begins as a small reddish papule or papular pustule which slowly increases in size and is soon capped with a crust There is epithelial hyperplasia giving the lesion a verrucous appearance Minute epidermal abscesses appear about the edges of the lesions and some lesions break down to form deep crater like ulcers with hard raised edges The subjective symptoms are mild pain is minimal and the patches are not sensitive to pressure The regional lymph nodes usually are not enlarged and the general health of the patient is not impaired so long as the disease is confined to the skin

Systemic Blastomycosis—Patients with primary pulmonary blastomycosis have fever night sweats loss of weight cough sputum which is frequently bloody leukocytosis increased sedimentation rate and physical and x ray evidence of extensive pulmonary disease The lesion usually is incorrectly diagnosed as pulmonary tuberculosis but it may be mistaken for primary bronchogenic carcinoma Sinus formation is rare as long as the disease is confined to the lungs but in the systemic cases where there are multiple lesions of the bones and involvement of the internal organs it is frequent and characteristic

Diagnosis—Cutaneous blastomycosis is readily diagnosed by its characteristic lesions but the diagnosis should be confirmed by finding the organisms in the pus

foci and multiple sinus formation There may be extension to the mediastinum esophagus and pericardium

Abdominal actinomycosis is found in 20 to 30 per cent of the cases and represents a highly fatal form of the disease The earliest signs are usually in the ileocecal region and are associated with the development of an indistinct irregular mass which is not painful as a rule and shows no characteristic features This may be the first manifestation of the disease or it may be preceded or accompanied by fever, chills night sweats intestinal colic and vomiting As the disease progresses there is usually involvement of the liver and spleen and symptoms of cystitis and pyelonephritis may appear Jaundice may be present Involvement of the central nervous system may occur in the terminal stages

Actinomycotic mycetoma is occasionally encountered and usually is caused by *Actinomyces asteroides* (See *Maduromycosis*)

Diagnosis —The diagnosis is based on the clinical syndrome, the finding of the sulfur granule in the exudate or lesion or the cultivation of the organism Biopsies of the sinus tract should be made when direct examination of the exudate fails to show granules Frequent and repeated study of the exudate both in fresh preparations and with the Gram stain is imperative Cultures are reliable in the yeast like mycoses but not in actinomycosis The cervicofacial forms must be differentiated from glanders tularemia tuberculosis and osteomyelitis The pulmonary form simulates tuberculosis pulmonary abscess tularemia and other mycoses The abdominal form may be mistaken for chronic appendicitis amebiasis typhoid fever carcinoma of the intestines tuberculosis liver abscess psoas abscess and sarcoma of the retroperitoneal tissue or of the iliac bones

Prognosis —The prognosis is best in the localized skin and cervicofacial types and becomes progressively worse with the thoracic abdominal generalized and neurologic types

Treatment —The general resistance of the patient should be supported as in tuberculosis by rest in bed and good food supplemented by vitamins especially cod liver oil and fruit juices The cervicofacial form should be treated by surgical drainage potassium iodide by mouth local x ray therapy and by sulfonamides Potassium iodide should be administered by the method prescribed for blastomycosis Ethyl iodide which is volatile, has been used successfully in some instances of pulmonary actinomycosis It is administered with an inhaler of the type made by Warren Collins Instrument Company of Boston The dose is measured in cubic centimeters in a graduated centrifuge tube attached to the instrument, and should begin with 0 25 cc t i d and increase by 0 25 cc every three or four days until as much as 1 cc t i d is being employed Colebrook advises either autogenous or stock vaccines as a supplement to the iodide therapy, giving a dose which contains from 5 000 000 to 10 000 000 mycelial fragments at intervals of five days

Sulfanilamide sulfathiazole and sulfadiazine have been used with some success in actinomycosis The best medical therapy is the combination of potassium iodide by mouth with sulfathiazole or sulfadiazine This treatment offers the only hope for abdominal and generalized infections and should be continued for three to five months

COCCIDIOIDAL GRANULOMA

Definition—Coccidioidal granuloma is a chronic generalized granulomatous disease with a high mortality The *primary* infection is analogous to the primary stage of tuberculosis

History.—Posadas and Wernicke recognized the disease in Buenos Aires in 1892 Rixford reported a case from California in 1894 and Rixford and Gilchrist studied a series of cases in 1896 In 1900 Ophüls and Moffitt cultivated the organisms and demonstrated that it was a fungus and not a protozoan

Incidence—The disease is encountered most frequently in southern California but may be found anywhere in the Southwest and appears to be spreading eastward Thousands of soldiers in the Army camps in the Southwest have contracted the benign primary infection and a certain number of them will probably develop the severe granulomatous type of disease in future years The disease occurs at all ages from three months to seventy years but is most prevalent between the ages of twenty five and fifty five In one series of 211 cases 83 per cent were in males

Etiology—The causative agent is *Coccidioides immitis* Emmons has shown that the organism is present in rodents in the endemic area and Meyer and Stewart succeeded in isolating the organism from the soil by guinea pig inoculations The organism may be introduced into man through a scratch or abrasion of the skin although the more usual method is inhalation which produces an atypical type of bronchopneumonia

Bacteriology—*Coccidioides immitis* multiplies in the tissues by endosporulation The organism is a sporule with a thick hyaline capsule varies from 11 to 70 microns in diameter and contains from 10 to 200 endospores When infected tissues sputum or other discharges are planted on Sabouraud s medium the endospores germinate and grow out as mycelia Laboratory infections have occurred by accidental inhalation of the chlamydospores from cultures

Immunology—All strains of *C immitis* apparently contain identical antigens During the course of the primary infection the patient develops precipitins and complement fixing antibodies and the skin becomes sensitive to coccidioidin The precipitins and complement fixing antibodies slowly disappear after recovery but the skin sensitivity, like that to tuberculin is relatively permanent

Pathology—In chronic coccidioidal granuloma the organisms are surrounded by epithelial cells giant cells lymphocytes and plasma cells Abscess formation is more frequent than in tuberculosis especially in the bones and subcutaneous tissues Occasionally granulomatous masses reach a considerable size without suppuration and resemble fibrosarcoma or fibromyxosarcoma Abbott and Cutler described three types of meningeal lesions one is practically identical with tuberculous meningitis a second has larger more granulomatous lesions and the third shows a thick accumulation of plastic exudate

Symptoms—In some areas in the Southwest positive skin tests with coccidioidin have been found in 50 to 84 per cent of the population indicating that primary infection with *C immitis* is very common but usually asymptomatic When the reaction to infection is severe enough to be recognized as a disease the symptoms signs x ray changes and course of the disease parallel that of primary tuberculous infection The patients have malaise anorexia chills fever headache backache night sweats and pleurisy The cough produces a scant amount of mucoid or mucopurulent sputum which contains the characteristic spherules of *C immitis* The organisms have been found in pleural fluid Roentgenograms of the lungs may show thickening of the hilar region peribronchial thickening or patches of nodular or bronchial pneumonitis The larger more solid lesions may break down and leave thin walled cavities which usually heal in a few weeks or months but may persist for

expressed from the small abscesses in the edge of the lesion, by culture or by biopsy In the systemic form the organisms can usually be grown from the sputum or from pus aspirated from a subcutaneous lesion A positive complement fixation is diagnostic but a negative test does not eliminate the possibility of the disease

Prognosis —The prognosis is good in cutaneous blastomycosis, but very poor for the pulmonary and systemic forms of the disease Martin and Smith found that 92 per cent of the patients with the generalized form of the disease had died within two years The prognosis in the pulmonary form can be improved by early diagnosis and prompt and adequate treatment Several patients treated in the Duke Hospital Clinic *have remained well for periods as long as* five to eight years

Treatment —Potassium iodide is the standard drug used for the cutaneous pulmonic and systemic forms of the disease but patients who have become sensitized to the products of the fungus as demonstrated by the presence of a positive skin test may show rapid progression of the disease after the administration of this drug If the patient is sensitive to a stock or autogenous vaccine he should be desensitized by the injection of gradually increasing amounts of the vaccine at forty eight to seventy two hour intervals for ten to fifteen doses before potassium iodide is given Both the nonsensitive patient and the desensitized patient should receive an initial dose of 3 drops t i d of a saturated solution of potassium iodide after meals The dose should be increased by 3 drops each day up to 30 to 40 drops t i d As much as 300 to 400 drops have been given in a single day Sensitivity to iodides may develop and necessitate the discontinuance of the drug After a rest period of seven to ten days it should be tried again

Ethyl iodide inhalations may be used as a supplement or as a substitute for potassium iodide The dose and method of administration is described in the section on actinomycosis

Sodium iodide may be administered intravenously and as much as 4 Gm per day have been given without harmful effects

Local x ray therapy for cutaneous blastomycosis has been highly successful in the Duke Hospital Clinic when given simultaneously with potassium iodide and subsequent to desensitization of the sensitive patient Local application of maggots was used successfully in one case of blastomycosis where the disease was limited to an osteomyelitis of the elbow

GEOTRICHOSIS

The bronchi and lungs and occasionally the mouth and intestinal tract may be attacked by one or more species of the genus *Geotrichum* The oral lesions resemble thrush and the pulmonary infection simulates blastomycosis Usually the patient has symptoms of bronchitis or of a rather mild but chronic type of bronchopneumonia In the more severe forms of the disease blood may be present in the sputum and cavities develop in the lungs The *Geotrichum* is frequently a secondary invader in chronic Friedlander's bacillus infection of the lungs and occasionally in tuberculosis

Bacteriology —The organism grows readily on Sabouraud s medium at room temperature and at 37° C There is a budding form of *Geotrichum* which is readily confused with the budding form of *Blastomyces* but this budding form is always accompanied by the rectangular conidia which are characteristic of the genus

Treatment —The oral lesions respond to the gentian violet treatment described for *Monilia albicans* The intestinal form should receive oral doses of gentian violet in salol coated capsules in doses of 32 mg t i d The bronchial and pulmonary forms have a

portal of entry is frequently in the area about the mouth there is ulceration of the intestinal tract and adenopathy severe enough to suggest Hodgkin s disease

The organism is found in the tissues as a large (10 to 30 microns) round doubly con toured form with multiple small buds about the periphery which were originally mis taken for endospores It grows readily on Sabouraud s medium and on blood agar Conant found that the method of growth and budding on blood agar was more like *Blastomyces dermatitidis* than *Coccidioides immitis*

The disease is usually fatal

The *treatment* suggested for coccidioidal granuloma should be given but supplemented by sulfonamides

CRYPTOCOCCOSIS

(*Torulosis*)

Definition —Cryptococcosis is a subacute or chronic highly fatal infection which may involve any part of the body but which has a marked predilection for the brain and meninges

History —In 1894 Busse and Buschke isolated from a fatal case with multiple lesions of skin and viscera, a yeast like organism which they called *Saccharomyces* but which has now been definitely identified as *Cryptococcus hominis* (*Torula histolytica*) This disease is called "blastomycosis" in the European literature and "European blastomycosis" in America, to distinguish it from American blastomycosis, or Gilchrist s disease which is caused by *Blastomyces dermatitidis* In the series of cases reported in this country by Stoddard and Cutler in 1916 under the name *Torula* there was no involvement of the skin Freeman collected forty three cases in 1931 Levine analyzed sixty cases in 1937 and Reeves and Butt seventy-one cases in 1941

Etiology —Cryptococcosis occurs in all parts of this country and in scattered areas throughout the world Benham has found nonpathogenic strains and strains of low pathogenicity on human skin

Bacteriology —*C hominis* grows readily on Sabouraud s medium the initial colonies appearing after four to twelve days incubation at 37° C The colonies are medium in size soft mucoid with a creamy color On examination the oval or slightly elongated cells 5 to 6 microns in diameter are surrounded by large capsules which are outlined clearly in india ink preparations This fungus multiplies by budding it does not form ascospores or mycelium

Immunology —Patients usually develop neither precipitins agglutinins nor complement fixing antibodies but filtrates from cultures have given positive kin tests of the delayed type

Pathology —Mook and Moore have described acneiform pustules granuloma like ulcers deep-seated abscesses and nodules which may increase in size and simulate myxomatous tumors Giant cells and 'foam cells are numerous fibroblasts lymphocytes and plasma cells are present but there is a remarkable paucity of poly morphonuclear leukocytes In several in stances the tissue reaction was very similar to that seen in Hodgkin s disease The central nervous system lesions may resemble tuberculous meningitis or there may be a diffuse granulomatous meningitis with the development of cyst like structures in the cortex The encapsulated organisms are present both in and outside of giant cells but there is an almost complete absence of leukocytes

Symptoms —The patient may present single isolated abscesses subcutaneous tumor like masses or multiple subcutaneous abscesses as in the original case of Busse and Buschke The primary pulmonary lesions resemble the more acute forms of re-infection tuberculosis but the lungs may present the picture of miliary tuberculosis in the generalized form of the disease

In the more common cerebral type of infection the onset is insidious with head ache dizziness vertigo and stiffness of the neck Occasionally the onset is sudden with violent and excruciating headache and

years Sensitivity to coccidioidin appears after seven to fourteen days and skin lesions resembling erythema nodosum or erythema multiforme develop in 2 to 5 per cent be tween the fifth and fourteenth day of the disease and persist for one to four weeks This form of the disease has been known for years as Valley fever Desert fever San Joaquin fever or as the bumps

Although recovery usually is rapid and complete an occasional case passes into the progressive virulent type of the disease with involvement of bones subcutaneous tissues and internal organs including the brain

Sometimes the organism gains entrance through the skin or possibly through the tonsils Lesions of the glands of the neck have been described which simulate tuber culous adenitis

The extensive rapidly fatal cases of coccidioidal granuloma are analogous to re infection tuberculosis and often develop years after the initial exposure The lungs usually are infected sometimes as the only organ involved but more often as a part of a generalized disease that includes bones joints vertebrae subcutaneous tissues in ternal organs and brain The roentgeno graphic shadows are easily mistaken for tu berculosis but the presence of bone and sub cutaneous lesions should suggest coccidioidal granuloma actinomycosis or blastomycosis

Diagnosis—One should suspect coccidi oidal granuloma in any obscure disease originating in a native of the endemic area and in individuals who have visited such areas *C immitis* can be found in the sputum in the case of primary infection In the re infection type the organisms are present in the sputum in the subcutaneous abscesses and in the lesions of the internal organs Precipitins and complement fixing anti bodies are present in a high titer in the pri mary cases but low or absent in the gran ulomatous cases The coccidioidin skin test is positive except in certain terminal anergic patients

Coccidioidal granuloma must be differen tiated from tuberculosis syphilis glanders bacterial osteomyelitis epithelioma and other mycoses

Prognosis—The prognosis is excellent in primary pulmonary involvement good in the dermal and glandular types of the dis ease when they are a part of the primary infection but most grave in the generalized and meningitic types

Treatment—Most primary pulmonary infections heal rapidly in a few weeks with out specific treatment The primary cases which have persistent thin walled cavities present a difficult problem Winn advises that conservative treatment be followed at home and surgery be avoided except pneu mothorax for the occasional patient with hemoptysis

The chronic generalized type of disease is difficult to treat Potassium iodide and vaccine therapy have been disappointing The best results have been obtained by Jacobson who uses colloidal copper supple mented with injections of coccidioidin Col loidal copper in 5 cc doses is injected deep in the gluteal region every four to seven days for ten to twenty five doses The coccidioidin injections may serve to reduce the patient s sensitivity

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis is a chronic gran ulomatous disease and is quite similar in its clinical course to coccidioidal granuloma

At the present time the disease is con fined to South America where De Almeida has collected the reports of 255 cases The

sence of polymorphonuclear, eosinophilic and lymphocytic reaction It seems probable that the lesions in the various organs result from masses of cells blocking the capillaries and producing localized necrosis The most extensive lesions occur in the liver spleen lymph nodes bone marrow and lungs

Symptoms —Very little is known of the symptoms presented by the patient in the early stages of the disease because most cases have been diagnosed postmortem or only shortly before death The terminal picture is characterized by splenomegaly hepatomegaly emaciation irregular pyrexia leukopenia and anemia Not all patients present this complete syndrome the liver and spleen may not be enlarged the disease may be confined chiefly to the lungs or even to the skin as in the case studied by Hansmann and Schenken

Diagnosis —The disease should be suspected in cases of unexplained splenomegaly and hepatomegaly especially if accompanied by irregular fever and leukopenia and anemia Dodd and Tompkins diagnosed their case before death by finding the characteristic organism in the monocytes of the circulating blood Repeated blood cultures should be made employing dextrose agar Sternal bone marrow punctures may furnish material for both direct examination and culture In pulmonary infections the sputum should be cultured and also inoculated into mice

Prognosis —There are no known recoveries

Treatment —Nothing specific is known about treatment Potassium iodide ionized copper and x ray therapy have been ineffective Sulfadiazine should be tried or possibly gentian violet intravenously in daily doses of 5 mg per kilogram of body weight

MONILIASIS

Definition —*Monilia* may produce acute or subacute infections of the mouth vagina, skin nails bronchi and lungs and occasionally a septicemia endocarditis or meningitis

History —The organism now known as *Monilia albicans* was discovered in oral thrush by Langenbeck in 1839

Etiology —The disease is found in all parts of the world at all ages in all races and in both sexes Oral thrush is most common in infants and in patients with wasting diseases Pregnancy and diabetes predispose to vaginal moniliasis Dermal lesions occur in bakers waiters fruit packers, bartenders and housewives whose hands are macerated from frequent soaking in water Poorly fitting artificial teeth predispose to infections of the tongue and mouth

Benham isolated both pathogenic and nonpathogenic strains of *Monilia* from normal skin and showed by animal experiments that *M albicans* is the only pathogenic species The various species of *Monilia* have been classified by Benham by Stovall and by Martin

Bacteriology —*Monilia* grow readily on Sabouraud s medium at room temperature or at 37° C and develop moist white elevated colonies with a distinct yeast like odor after two to four days incubation *Monilia albicans* is lethal for rabbits ferments certain sugars agglutinates in specific sera and forms typical chlamydospores on corn meal agar

Immunology —Positive skin tests of the tuberculin type are frequently present but are not diagnostic because they occur in normal individuals The immediate (twenty minutes) wheal like skin test occurs occasionally in all types of monilia infections but most frequently in patients with bronchial asthma

vomiting The patient has little or no fever and the pulse and blood pressure remain normal The disease often is mistaken for a rather chronic type of tuberculous meningitis *After several weeks or months* more severe symptoms and signs appear, such as neuroretinitis papilledema, strabismus nystagmus ptosis, diplopia ataxia or hemiplegia The patient ultimately becomes comatose and dies of respiratory failure

Diagnosis—The dermal, subcutaneous and glandular lesions may be diagnosed by routine biopsies and cultures on Sabouraud s medium The diagnosis of the pulmonary forms is made by growing the organism from the sputum In the meningeal form of the disease the spinal fluid pressure is increased and the spinal fluid usually contains 200 to 800 cells which are chiefly mononuclear The spinal fluid sugar is decreased The *Cryptococci* are present in small numbers and are readily mistaken for red cells or lymphocytes After centrifugalization the sediment from the spinal fluid should be planted on Sabouraud s medium and watched for three or four weeks Not infrequently the organism can be found by direct examination if a drop of the sedimented material is mixed with india ink

Prognosis—The prognosis is grave in all forms of the disease, especially the cerebral form which *until recently has been considered* inevitably fatal

Treatment—The local lesions are treated by surgical excision or drainage supplemented by local x ray therapy and potassium iodide by mouth (see Blastomycosis) Repeated lumbar punctures diminish the symptoms of patients with cryptococcosis of the central nervous system Recently Mar*shall and* Teed reported the recovery of a patient following intensive treatment with sulfadiazine

HISTOPLASMOSIS

Definition—Histoplasmosis is characterized by emaciation splenomegaly, hepatomegaly, leukopenia, anemia and irregular pyrexia

History—In 1906 Darling in Panama, found round or oval parasites in *the* endothelial cells and monocytes of certain cases of splenomegaly He thought the organisms were protozoa and suggested the name *Histoplasma capsulatum* In 1934 Dodd Tompkins and De Monbreun isolated the organism from a typical clinical case in a child and found it was a fungus Earlier in the same year *Hansmann* and Schenken isolated a fungus from a patient with a refractory skin infection which later was found to be identical with the De Monbreun culture More than thirty cases have been diagnosed in this country in the past eight years

Etiology—Histoplasmosis has been found in Central America Java and throughout the United States All races seem susceptible both sexes are attacked at all ages but children seem to be relatively more *susceptible* than to other mycotic infections De Monbreun found a dog with a spontaneous infection

Bacteriology—The organism can be isolated directly from the blood from the sternal bone marrow or from tissues at necropsy by planting the material in dextrose agar or dextrose broth at 37° C Two *types of colonies appear a mycelial* type and a yeast like type The mycelial form is less pathogenic but when infection is induced by intraperitoneal inoculation in the mouse the organism reverts and the yeast form can be recovered

Pathology.—Histoplasmosis is primarily a disease of the reticulo endothelial system The organisms are found in the cytoplasm of circulating monocytes in the tissue phagocytes of the various organs in the lymph nodes bone marrow and in the endothelial cells of small lymph and blood vessels and capillaries There is a conspicuous ab

outlined in the section on Blastomycosis In some cases the patients have positive skin tests to *Monilia* vaccines and may not respond to the iodides until partial desensitization with vaccine has been effected Intravenous gentian violet in doses of 5 mg per kilogram of body weight each day or every other day for four to six doses sometimes cures massive pulmonary infections

SPOROTRICHOSIS

Definition—Sporotrichosis is a chronic infection characterized by the formation of gumma like nodules abscesses and ulcers The lesions usually are confined to the skin and superficial lymph nodes

History.—Schenck in 1896 isolated a fungus later identified as *Sporotrichum* by E F Smith from a patient in Johns Hopkins Hospital The second case was described by Hektoen and Perkins in 1900 who named the fungus *Sporotrichum schenckii* The disease was recognized in France in 1903 by de Beurmann and Raymond and their organism was named *Sporotrichum beurmanni* by Matruchot and Raymond

Etiology—The disease occurs throughout the world but most often in males especially farmers laborers and horticulturists The primary lesion was on some part of the upper extremities in 90 of 102 cases Sporotrichosis occurs spontaneously in horses dogs and rats Meyer infected himself while working with an equine strain Benham and Kesten s transmission of the infection to carnations *with a culture isolated from man* suggests that plants may act as intermediate hosts

Bacteriology—The organism grows readily on Sabouraud s honey agar or on plain meat extract dextrose agar, at room temperature or at 37° C The growth appears after five to ten days incubation and shows small white colonies which slowly enlarge and then become brown or black

Immunology—Agglutinins and complement fixing antibodies may appear in the serum and occasionally the patient develops a tuberculin like sensitivity

Pathology—The gumma like nodules usually consist of a central abscess surrounded by granulation tissue with giant and epithelioid cells and a peripheral zone of connective tissue histologically resembling syphilitic tuberculous or other chronic inflammations In the living tissue *Sporotrichum* occurs as oval bodies of fairly uniform size 2 to 3 microns broad and 3 to 5 microns long

Symptoms—The primary lesion usually is in the skin and may appear as early as twenty days or as long as three months after the initial infection The primary lesion is a hard spherical elastic movable subcutaneous nodule and not adherent to the overlying skin It becomes attached to the skin which first becomes pink and then purplish and finally black and necrotic This lesion (sporothrix chancre) may persist for months Usually after a few days or weeks multiple subcutaneous nodules appear along the course of the lymphatic drainage These nodules are at first freely movable but later adhere to the overlying skin become reddened and ulcerate through to the surface discharging a small amount of thin pus The lymph vessels between the nodes may become so thickened they can be felt as hard cords

The clinical types of the disease have been classified by de Beurmann and Gougerot as (1) lymphatic (2) disseminated (3) epidermal (4) sporotrichosis of the mucous membranes (5) skeletal sporotrichosis and (6) visceral sporotrichosis In the rare disseminated gummatous form single or successive crops of nodes develop at intervals Forbus found only two reported cases in which the evidence of pulmonary involvement was in any way satisfactory

Precipitins and agglutinins usually but not always are present in pulmonary and generalized moniliasis

Pathology—Both budding cells and mycelial threads are found in scrapings from the dermal and mucosal infections In the lungs and other internal organs focal areas of necrosis are found which contain budding cells with or without mycelium Giant cells may or may not be present The cellular reaction is one of polymorphonuclear leukocytes, monocytes and lymphocytes

Symptoms—White patches in the mouth or vagina should suggest the possibility of *thrush* or *vaginal moniliasis*

Paronychial and *onychial* infections are fairly common

Dermal lesions in malnourished infants usually begin about the anus and over the inguinal or crural region and may be vascular, pustular or erythematous and squamous

Intertriginous moniliasis is rather common and may be seen at any age It is characterized by a primary erythematous vesicle or pustule which extends peripherally and forms plaques with irregular borders These are separated from the normal skin by heaped up accumulations of whitish epithelium

Dyshydrosiform eruptions may develop in individuals whose feet and hands perspire abnormally The lesions consist of discrete vesicles which resemble closely those seen in certain types of epidermophytosis

Generalized eruptions in patients subjected to continuous water bath therapy may develop over the palms nails axillae knees and genital regions Dark red infiltrated papules appear which become confluent and form large plaques with irregular borders

Glossitis occurs occasionally and may result in hypertrophied somewhat blackened papillae or the papillae may be replaced by a hard white patch

Bronchitis both the acute and chronic varieties result from bronchial infections The symptoms resemble those of bacterial bronchitis but the sputum usually is mucoid or gelatinous

Pneumonitis occurs as an acute or subacute process The lungs may show massive patchy consolidation in one or more lobes There is cough malaise fever and leukocytosis but usually the patients are less toxic than with bacterial infections The sputum is mucoid or mucopurulent and may contain blood

Diagnosis—The skin lesions are diagnosed by finding *Monilia* in the scrapings or on culture It is impossible to find *Monilia* in some of the vesicular lesions and it is probable that these are allergic reactions analogous to the 'ids' in epidermophytoses

The bronchial and pulmonary lesions are diagnosed by growing *M albicans* the one pathogenic species from the sputum Even *M albicans* may be an accidental contaminant from the mouth or bronchi or a secondary invader in tuberculosis carcinoma or some other mycoses If there are agglutinins in the patient s serum in a dilution of more than 1 to 80 the diagnosis of moniliasis probably is correct but agglutinins may not be present in the early weeks of extensive pulmonary infections

Prognosis—The acute dermal lesions respond well to treatment The recurrent type is more resistant The acute types of glossitis and stomatitis heal readily but the chronic type of glossitis may persist for years Patients with bronchial and pulmonary forms of the disease usually recover although occasionally the pulmonary form is fatal

Treatment—The cutaneous lesions should be kept dry especially those precipitated by excessive wetting Local applications of potassium permanganate (1 1500) or soaking in the solution for thirty minutes twice each day usually cures the dermal lesions If this is not successful mercurochrome in a 2 per cent solution or alcohol (50–70 per cent) should be applied daily Ointments such as chrysarobin (1–2 per cent) or crude tar (2–6 per cent) have been used The oral lesions usually respond to alkaline washes or to gargles with 1–10 000 gentian violet Potassium permanganate (1 1500) or gentian violet (1 10 000) douches are used for the vaginal lesions X ray therapy has been used successfully for onychia and paronychia If perleche does not respond to local treatment vitamins should be administered (riboflavin 10 mg daily pyridoxine 50 mg daily or yeast 15 Gm daily)

Bronchial and pulmonary moniliasis should be treated with potassium iodide as

are confined to the feet and legs but may be limited to the hands and arms In 1911, Pedroso of S10 Paulo Brazil isolated a pigmented organism from patients with verrucous lesions of the skin which was later named *Hormodendrum pedrosoi* Large spherical bodies dark brown in color are present in abundance in the verrucous lesions and grow readily on Sabouraud s medium

Pathology —The disease is very chronic and may last for years With the development of extensive fibrosis in the deeper dermal lesions the lymphatics are blocked and the patient develops an elephantiasis of the extremity

Treatment —Complete destruction of the lesion by surgical excision or electrotherapeutic methods would seem to be logical when the disease is diagnosed in its incipient stage Surgical amputation is not justifiable because the lesions rarely become severely infected and usually make sufficient response to medical treatment to leave the patient with a useful limb The internal treatment consists of large doses of potassium iodide up to as much as 1 to 9 Gm per day Iontophoresis with copper sulfate was employed with considerable success in the case reported by Martin Baker and Conant

ASPERGILLOSIS

Certain species of Aspergilli especially *Aspergillus fumigatus* produce inflammatory granulomatous lesions in the skin external ear vagina nasal sinuses orbit bronchi lungs and occasionally bones and meninges The disease was first recognized by Bennett in 1842 and the first careful necropsy of pulmonary aspergillosis in man was by Virchow in 1856 Renon s monograph published in 1897 established the frequency and importance of aspergillosis in France Extensive pulmonary lesions may occur in instances where there are overwhelming exposures to the spores as in pigeon feeders hair cleaners and certain agricultural workers Aspergilli grow readily on dextrose agar or Sabouraud s medium at either room temperature or at 37° C Infection may be suspected from the greenish or brown color of the discharges Aspergilli are frequently secondary invaders or accidental contaminants and the diagnosis should not be made exclusively on the appearance of the organism on culture One should demonstrate the mycelial forms directly in the discharges before the material is planted The standard treatment is potassium iodide If hypersensitiveness to an autogenous aspergillus vaccine can be demonstrated then vaccine therapy is also indicated For superficial lesions thymol iodide dusting powders or 2 per cent thymol in 70 to 95 per cent alcohol may be employed

PENICILLIOSIS

Several species of the genus *Penicillium* are capable of producing lesions in the ear and skin and occasionally in the lungs Clinically the infections resemble those caused by the *Aspergillus* and the same care has to be exercised in establishing the etiologic relationship between the culture and the disease The *treatment* is the same as for aspergillosis

David T Smith

Diagnosis—The diagnosis is established by cultivating the organisms from the discharges or from material removed at biopsy The disease may simulate syphilis tuberculosis blastomycosis cryptococcosis glanders, tularemia leprosy *or pyogenic infections*

Prognosis—Uncomplicated sporotrichosis is rarely fatal, when untreated it persists *for months or years but* appropriate treatment usually is followed by rapid healing

Treatment—Potassium iodide should be given in slowly increasing doses up to 4 to 6 Gm or more daily If absorption of closed abscesses is slow, they may be punctured aspirated and injected with a weak solution of iodide Incision and curettage are to be avoided Ulcerated lesions may be painted with tincture of iodine and dressed with a solution containing water 500 cc potassium iodide 10 Gm and iodine 1 Gm The treatment should be continued for at least a month after apparent recovery

MADUROMYCOSIS

(*Madura Foot*)

Maduromycosis or mycetoma is a chronic infection affecting principally the foot but in rare instances other parts of the body It is characterized by multiple abscesses and sinuses and the development of granulation and connective tissues

Bacteriology—Carter in 1860 proved that the disease was a mycosis and introduced the term mycetoma or fungus tumor The disease may be caused by any one of thirteen species of the genus *Actinomyces or any one of nineteen* species of molds belonging to two classes and eight genera (Gammel)

Etiology—The specific cause is contained in the white, yellow, deep brown or black granules which appear in the discharges from the affected region The disease is most common in males and in farmers or other individuals who come directly in contact with the soil

Pathology—The pathologic reaction is essentially the same regardless of the type of invading fungus There is local and general swelling of the parts affected with a corresponding degree of deformity In old chronic cases the skin is darkened and the surface studded with pitted scars open sinuses and nodular fungating elevations Dense masses of scar tissue are found in the healing lesions The abscesses connected with the sinuses are filled with mucoid fluid in which the characteristic granules are floating

Prognosis and Treatment—Maduromycosis does not heal spontaneously The disease continues to progress and the patients eventually die of secondary infection if the disease process is not eradicated by excision or amputation Sulfonamide therapy is a useful supplementary treatment

CHROMOMYCOSIS

Chromomycosis or verrucous dermatitis is characterized by the formation of warty cutaneous nodules which through slow progressive growth become transformed into prominent papillomatous vegetations which may or may not ulcerate Usually the lesions

are confined to the feet and legs but may be limited to the hands and arms In 1911, Pedroso of São Paulo Brazil isolated a pigmented organism from patients with verrucous lesions of the skin which was later named *Hormodendrum pedrosoi* Large spherical bodies dark brown in color are present in abundance in the verrucous lesions and grow readily on Sabouraud's medium

Pathology —The disease is very chronic and may last for years With the development of extensive fibrosis in the deeper dermal lesions the lymphatics are blocked and the patient develops an elephantiasis of the extremity

Treatment —Complete destruction of the lesion by surgical excision or electrotherapeutic methods would seem to be logical when the disease is diagnosed in its incipient stage Surgical amputation is not justifiable because the lesions rarely become severely infected and usually make sufficient response to medical treatment to leave the patient with a useful limb The internal treatment consists of large doses of potassium iodide up to as much as 1 to 9 Gm per day Iontophoresis with copper sulfate was employed with considerable success in the case reported by Martin Baker and Conant

SPIROCHETAL INFECTIONS

SYPHILIS

Definition —Syphilis is a specific infectious disease of protean manifestations caused by the *Treponema pallidum* It may be acquired or congenital The *acquired form* is characterized by an initial sore and an early stage of invasion with relatively mild systemic disturbance and by eruptions upon the skin and mucous membranes After a variable interval there follows a late stage of specific granulomata connective tissue proliferation with destruction of parenchyma and disturbance of the function of various organs The *congenital form* is similar in its pathology except that there is no primary lesion and the late manifestations predominate

History —There are two opposing views concerning the antiquity of syphilis One is that the disease was introduced into the civilized world in relatively recent times by the returning sailors of Columbus and that it was spread throughout Italy in 1493 by the soldiers of Charles VIII It was about this time that the disease became a great scourge and spread rapidly over Europe The other view is that syphilis is a very ancient disease which has existed among civilized peoples since the very dawn of history Early Egyptian and Assyrian inscriptions as well as the bony changes found in mummies are cited as documents in evidence The controversy continues

The syphilis of the Middle Ages was virulent and widespread Its rapid propagation at this time was effected by various modes of personal contact and its venereal origin was not generally recognized Later syphilis came to be regarded solely as a venereal disease but the hard chancre the soft chancre or chancroid and gonorrhea were not distinguished for a long time They were differentiated by Ricord

Then there came in the nineteenth century a period when syphilis was studied largely in its dermatologic aspects Although the dermatologists of the day (Ricord Hebra Fournier and others) understood the general character of the infection the graphic appearances on the skin and mucous membranes seemed in their minds to dominate the clinical picture and to give the disease special dermatologic interest

In the early part of the twentieth century the conception of syphilis was greatly broadened and the disease gradually assumed a different clinical aspect Experimental study was facilitated by the discovery of Metchnikoff and Roux that syphilis can be transmitted by inoculation to the lower animals In 1905 Schaudinn made the epoch making discovery of the causative agent, the *Treponema pallidum* About a year later Wassermann devised the biologic reaction of great diagnostic value to which his name has been given In 1910 Ehrlich in his studies in chemotherapy succeeded in producing the highly potent remedy salvarsan (arsphenamine) Finally in 1913 the much discussed question of parasyphilitic disease was settled by Noguchi when he demonstrated the constant presence of the treponema in the brain of paretics As a result of these discoveries syphilis is now recognized as a general disease with protean manifestations For the first time its menace has been given widespread publicity and its spread is being combated by public health agencies everywhere

Incidence —The generally accepted estimate that, taking the population as a whole 10 per cent of adult Americans have syphilis is probably accurate but there are enormous differences For example of the private patients I see less than 1 per cent have syphilis and of the Negroes in the medical wards of the hospital more than 25 per cent are infected A good picture was given by Usilton and her associates in their studies of one of the largest American cities wherein it was revealed that 44 persons per ten thousand are constantly being treated for this disease and that of 15 000 who seek such treatment each year only 2500 have early syphilis

Etiology —The *Treponema pallidum* was first discovered by Schaudinn and Hoffman in the tissue fluids of an initial syphilitic lesion Subsequently its causative relation to syphilis was abundantly proved both by these investigators and by others Koch s

postulates have been fulfilled This treponema is a delicate spiral corkscrew' organism 6 to 20 microns in length actively motile and difficult to stain It is claimed the organism is polymorphous and that granular and other forms exist but this has not been substantiated It can perhaps best be classed among the protozoa

The parasite is found in abundance in the tissue fluids and secretions of the primary lesion During the early stages it is present in large numbers in the lymph nodes particularly in those nearest the initial sore Later it may be found in the roseola and other skin lesions as well as in the inner organs During the so called secondary stage it has been found in both blood and spinal fluid Treponemas have been demonstrated in the scars of syphilitic lesions long after healing The apparently healthy tonsils of untreated syphilitics have been shown to harbor the organisms in abundance In general it may be said that during early syphilis there is an invasion of the entire body so that treponemas are present in abundance in practically all of the organs in late syphilis the infection is more localized and smaller numbers of the organism are found in the parenchyma of the diseased organs Treponemas can seldom be found in the specific granulomas of the late stages but are encountered in relatively small numbers in the apparently healthy surrounding tissue They are found in greatest abundance in the tissues and organs of infants with congenital syphilis Outside the body the treponema dies quickly It is rapidly destroyed by ordinary soap

Modes of Transmission—Syphilis is most often transmitted by sexual intercourse but other forms of personal contact such as kissing the nursing of an infant by an infected wet nurse or the examination by the physician of an infected patient also spread the disease Although extragenital chancres may be found on any part of the body they are usually located on the lip and the finger Indirect contact such as comes from the use of a common instrument by glass blowers musicians etc or a common drinking cup is sometimes a mode of transmission The extragenital chancre is particularly dangerous because its true nature is often unrecognized and no precautions are taken to prevent transmission In localities where syphilis appears to be endemic and to afflict almost the entire population the extragenital method is probably the most common form of transmission Infection most often results from contact with the chancre or mucous patch although it can be derived from almost any syphilitic lesion The earlier the lesion the greater the chance of infection

The treponema is believed by many to produce invariably an initial sore at the point of entrance, but there is good evidence that at times it passes through the apparently unbroken skin without producing a chancre

Congenital syphilis is transmitted by the mother If the infection originally comes from the father the mother is first infected and then after acquiring the disease she transmits the treponema through the placenta to the fetus

Morbid Anatomy—The primary sore or chancre is a local inflammatory lesion characterized by infiltration with lymphocytes and plasma cells, these cells accumulate in the tissues and around the blood vessels and block the lymph vessels This obliteration of arteries veins and lymph vessels is especially characteristic of syphilis Interference with the blood supply leads to retrogressive changes Finally only a scar remains

Even before the chancre has fully developed the treponema invades the neighboring lymph channels and thence finds its way into the general circulation Local lymphangitis and lymphadenitis are therefore early lesions The roseola and other skin manifestations which develop a little later represent a reaction of the skin to the presence of the treponema

Other so called secondary lesions may be found in any of the organs Obliterative arteritis as well as phlebitis and round cell infiltration accompanies all the early changes At this stage the fixed tissues with the exception of the vessels are not extensively destroyed

In late syphilis on the contrary not only are the vessels involved but there is extensive destruction of parenchyma with an overgrowth of fibrous tissue This chronic interstitial inflammatory reaction presents

no peculiarly characteristic features except perhaps the invariable obliterative arteritis and phlebitis Diagnosis is often facilitated, however by the presence of the gumma—the characteristic lesion of late syphilis

The gumma is a granuloma or conglomeration of granulomas in the formation of *which an infiltration of lymphocytes and* a few epithelioid and plasma cells plays the chief role connective tissue proliferation obliterative endarteritis phlebitis and necrosis also take place The gumma is often soft in the center and exudes semisolid debris It may be of almost microscopic size or a large tumor several centimeters in diameter After it breaks down scar tissue usually forms

The most characteristic histologic feature of syphilis is the involvement of the blood vessels This consists at first of an intense round cell infiltration in the adventitia and in the *vasa vasorum* which may spread evenly along the vessel wall or may appear as irregularly placed nodules All syphilitic lesions are said to have their beginning in the walls of the blood vessels In their studies of experimental syphilis Cunningham and his associates were impressed by the phagocytic activity of the mononuclear cells of the tissues They concluded that these cells play an important part in the resolution of syphilitic lesions

The Course of Syphilis—From the very beginning syphilis is a general disease in which the entire body is involved The treponema enters through the skin or mucous membrane and produces at the point of entrance a characteristic tissue reaction—the chancre or papule An abrasion or other lesion favors but it is not essential for infection, for the organism can unquestionably enter the apparently unbroken skin

The chancre appears within from ten to ninety days after infection usually after about three weeks Even during this *first incubation period* before the ulcer can be seen the infection begins to spread throughout the body The treponema early gains entrance to the lymph vessels and invades the blood stream

After the appearance of the chancre there is a *second incubation period* of variable length (usually six weeks to six months) during which there are no symptoms except, possibly, secondary anemia and enlargement of the regional lymph nodes Important changes however are taking place at this time The treponemas are making good their invasion of the tissues and the body is developing defensive reactions which *lead* to the presence of antibodies in the blood

The end of this secondary incubation period is marked by the appearance of typical *eruptions of the skin and mucous membranes* This has been termed the secondary period of syphilis The eruption quickly disappears with treatment, but in untreated cases may persist a long time with gradual change During this stage treponemas may be found in the blood stream and cerebrospinal fluid and in a large number of patients cellular changes provide evidence of cerebrospinal involvement The other evidences of general involvement are described below

The eruption and other symptoms of this period may be so slight as to escape notice or may be absent altogether Many observers think that when this is the case the infection finally develops into the most malignant late type but their belief is doubtless due in part at least, to the fact that the asymptomatic type escapes treatment and consequently develops unhindered Treatment at this time causes a disappearance of all symptoms and if therapeutic measures are prompt energetic and sustained relief is as a rule, permanent Occasionally the eruption may recur once or twice in the same areas and even a *chancre redux'* may appear During this early period syphilitic processes are no doubt also taking place in the internal organs but they are relatively benign and produce few clinical signs

At the end of the secondary period especially in patients who have been inadequately treated there usually ensues a so called *latent period* This in turn is followed by the *tertiary* or *late period of visceral syphilis* The latent period may persist for only a few weeks or for twenty or thirty years It usually lasts for five to seven years The late manifestations which are deep seated and destructive may involve any of the organs and often endanger the patient's life Included among them are many ner

vous manifestations notably paresis and tabes dorsalis

This classical division of the course of syphilis into three stages is arbitrary and does not accord fully with our present understanding of the disease The secondary eruption may appear while the chancre still flourishes tertiary visceral manifestations may be produced by gummas during the period of florid secondary syphilis and the secondary period may merge imperceptibly into the tertiary stage or be missed entirely More rational therefore is the division of the disease into two stages early syphilis which includes the primary lesion and the so-called secondaries and late or visceral syphilis Although the dividing line between the two stages is not always sharp certain features of each warrant this distinction The *early stage* is characterized by the presence of a large number of treponemas in the lesions by the prompt response to treatment by lack of response to the administration of iodides and by the tendency of the lesions to heal without scars *Late* or *visceral syphilis* is characterized by the presence of a small number of organisms in the lesions by extensive destruction of parenchyma by the formation of gummas and connective-tissue proliferation by ready response to the iodides and by the formation of scars

Symptoms —In the following pages syphilis will be discussed as a continuous general infection with two types of manifestation the one occurring early and the other as a rule late

Acquired Syphilis —The *chancre* develops at the site of entrance of infection after an incubation of from ten to ninety days usually within about three weeks As a rule it is on the genital organs It appears first as a small papule which soon erodes into a reddish ulcer often covered by a grayish yellow exudate This is usually somewhat elevated but not excavated is distinctly circumscribed and has little or no areola of inflammation It is important to remember that the often described hard or shotlike consistency of the chancre cannot usually be detected for one or two weeks after onset The chancre may first appear as a simple erosion without induration The classical *hunterian chancre* is deeply ulcerated with a raised (not excavated) border and a cartilaginous consistency On the other hand the initial lesion may never ulcerate but remain merely a papule Most patients have only one chancre but when two mucous surfaces come in contact the lesion may in rare instances be multiple It is rarely painful and may, consequently pass unnoticed If not contaminated with chancroidal infection the chancre usually heals without treatment in four to six weeks Phagedenic ulceration sometimes occurs in very debilitated persons or when the lesion is both a chancre and chancroid (See *Diagnosis*) The chancre leaves a scar which usually persists several months The so-called *chancre redux* is caused by organisms which remain

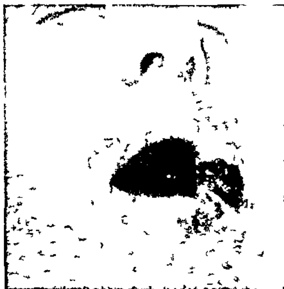

Fig 32 —Chancre of the lip (Courtesy of Dr Andrew L. Glaze)

in this scar Extragenital chancres may appear almost anywhere on the body—the finger lip eyelid tonsil nipple and tongue being its most frequent sites

A chancre is always accompanied by involvement of the lymph vessels and swelling of the regional lymph nodes which become palpable about three or four weeks after infection They are discrete and hard Unless the infection is mixed they do not suppurate

General Symptoms —While the chancre is disappearing and during the second incubation period the patient experiences a few vague symptoms There is usually moderate anemia and swelling of the general

lymph nodes Toward the end of this period just before the eruption symptoms of a more pronounced nature appear, many of which are common to all bacterial invasions The secondary anemia with pallor increases About a third of the patients have a low-grade fever which is often intermittent There is more or less physical and mental depression Pains in the bones and joints are frequent and sometimes severe The patient may complain of cardiac palpitation arrhythmias and other circulatory disturbances *On the other hand, he may feel surprisingly well* As the rash appears the severity of all these symptoms increases The fever is more constant and the temperature is perhaps higher the lassitude is more noticeable, and the patient may lose weight There is headache and pain in the bones and joints especially at the insertions of the tendons The spleen may or may not be palpable Icterus is frequent, and occasionally there is recognizable enlargement of the liver Iritis, and inflammation of various nerves particularly of the optic and auditory nerves may occur at this time Exaggeration of the reflexes is often noted, and rarely there may be a genuine syphilitic meningitis This stage is said to coincide with the most widespread distribution of the treponema throughout the body

THE SKIN AND MUCOUS MEMBRANES — The eruption of syphilis is manifold in character and can simulate practically any skin disease *Certain characteristics are however* common to all syphilitic skin manifestations they are usually symmetrical when papular the eruption is often arranged in circles or segments of circles which follow the distribution of the blood vessels they are often polymorphic consisting of two or more types of eruption at the same time, and unless irritated or otherwise complicated they do not cause pain or itching There are three main types of syphilitic eruption the macular papular and tubercular

(A) THE MACULAR ERUPTION —The macular eruption or roseola ordinarily is the first to appear It is seen usually on the abdomen and chest *the face often escapes* The rash may be nothing more than a faint diffuse blush or may consist of clearly defined rose-colored macules of varying size The dilated capillaries which produce *this* eruption contain large numbers of treponemas and the *blood taken from a roseola spot* or the fluid which exudes from the skin on injury, is highly contagious The roseola disappears within one or two weeks Another type of macular eruption often appears a little later, but may develop at the same time The macule of this type is slightly elevated persists longer than the other, is copper colored and in fading, often leaves a transiently pigmented spot or a faded area

(B) THE PAPULAR ERUPTION —The size of *the papule* varies greatly The lesion consists of the infiltration of small areas which are at first generally distributed over the body but later tend to become localized particularly around the genitals and anus In such locations the papules are inclined to become broader and to assume a wart like character They are then called *condylomata* Papules may appear on the palms of the hands or the soles of the feet as slight depressions When the scales which cover them are removed they are seen to have a reddish coppery color They are indurated and tend to crack open and ulcerate These *palmar syphilids* may develop in the late as well as in the early stages Papules occasionally destroy the nail bed and lead to a syphilitic onychia and paronychia which is most refractory to treatment The hair often drops out sometimes in patches giving a moth eaten' alopecia

The most characteristic persistent and *infectious of all syphilitic eruptions* the *mucous patch* is papular in character It develops on the mucous membranes of the mouth tongue tonsil prepuce and vagina as a slightly elevated glistening circumscribed area with a depressed center It is free from induration and is usually covered with a white or yellowish exudate These patches often coalesce to form large irregular areas They may persist for months and may continue to recur for many years

Papules occasionally suppurate and give rise to a pustular eruption This seldom occurs early and may be considered a more severe lesion than any of those already described The pustules tend either to dry up and become covered with brownish red crusts or to break down and form large ulcers Several varieties are described one *resembles acne* another *variola* there is a

third form called *impetigo syphilitica* and a fourth known as *ecthyma syphiliticum* in which there is extensive suppuration and ulceration

(c) THE TUBERCULAR ERUPTION—The tubercular or nodular syphilid often develops during an intermediary stage between early and late syphilis its histology being more typical of the latter condition This lesion consists of small discrete elevated nodules of a bluish red or ham color which tend to appear in circles and spreading at the periphery to unite and form serpiginous and other configurations As the nodules disappear they leave an atrophic brownish area which later becomes white In the more severe forms the nodules tend to become confluent When they appear late in the disease they often ulcerate They may persist many years

True *gummas* appear in the skin and subcutaneous tissues during late syphilis They often coalesce and ulcerate and thus produce large areas of necrosis The exudate from such an area dries and forms a crust continued exudation leads to the formation of another crust beneath this yet another and so on until a crust of many layers appears Other lesions may appear in the mouth throat or nose at any stage of the disease The tonsils frequently and less often the larynx are subject to these processes A characteristic feature of the mouth lesions is their tendency to recur and persist for many years They are highly contagious

There is no sharp dividing line between the early and the late skin lesions of syphilis The essential difference is that the latter are more local in character more chronic more liable to ulcerate and much more destructive than the early manifestations

THE BONES—During the early stages of syphilis the patient often complains of *pains in the bones* The headaches and neuralgias of syphilis are often due to involvement of bone it is possible as the result of vascular obliteration for necrosis and caries of the cranial bones to take place even in the early stages although at this time lesions in the bones are rarely demonstrable It is in late syphilis that the bone lesions are most apparent and more destructive Periostitis particularly of the long bones is frequent It is usually accompanied by pain redness and diffuse swelling The lesion may become absorbed but often stimulates the formation of new bone of extreme hardness as in the characteristic *saber shin* (periostitis of tibia) Exostoses are also common *Gummas* frequently form in the bone during late syphilis Destruction of the bones of the face and nose are often the result of such gummatous processes *Syphilitic dactylitis* characterized by a peculiar smooth bluish swelling of the phalanges sometimes occurs *Involvement of the vertebrae* may lead to pain on movement stiffness or deformity The pains of syphilitic bone disease are more intense at night and are said to be often relieved by exercise

A true *arthritis* may be an early manifestation of syphilis This may suggest tuberculosis or when of an acute polyarthritic nature rheumatic fever In late syphilis several types of monarthritis occur Involvement of the knee joint which may cause the formation of a *tumor albus* is difficult to distinguish from tuberculosis

THE CIRCULATORY SYSTEM—Involvement of the heart and aorta by the spirochete is frequent In their studies of 1000 syphilitic patients Cochems and Kemp found cardiovascular syphilis in 10.8 per cent of the women and 13 4 per cent of the men with a gross incidence of 12 7 per cent These figures are in essential agreement with those of other investigators

Early in the disease various cardiac disturbances may take place—tachycardia bradycardia and arrhythmia The heart is easily excited and quickly exhausted Undoubtedly early syphilitic myocarditis does occur but there is some question as to how often the above described condition represents true myocarditis Later gummas and interstitial inflammatory changes appear in the myocardium A gumma of the bundle of His with the threat of sudden death is a common cause of Stokes Adams syndrome Fibrous replacement of the myocardium as the extension perhaps of a process beginning in the coronary arteries is also common The symptoms are the same as those of myocardial disease from other causes except that cardiac failure may come with considerable abruptness and that disturbances of rhythm are relatively rare

Syphilitic aortitis which is often limited

to the thorax and usually begins near the root of the vessel, is a common disease, but unfortunately when uncomplicated it presents no recognizable signs, significant roentgenographic appearances are also wanting It frequently leads to aneurysm

Aortic insufficiency, which often follows aortitis pursues a variable clinical course The cor bovinum the water hammer pulse the murmur along the left border of the sternum, and the evidences of myocardial failure are described elsewhere in this book The characteristic electrocardiographic signs listed by Blackford and Smith are left axis deviation, defective interventricular conduction, low voltage of the T wave and deviation of the ST segment The sudden onset of cardiac failure, precordial pain and respiratory distress without edema are, according to the *same authors*, signs of *ominous* prognostic significance

THE RESPIRATORY ORGANS —In early *syphilis*, mild disturbances in the upper air passages are frequent and cause hoarseness and coughing Later deeper and more destructive processes occur Single gummas or more frequently, diffuse gummatous infiltrations develop and often break down into deep seated ulcers Hoarseness and aphonia commonly result Such syphilitic processes can as a rule be distinguished from tuberculosis by the relative paucity of subjective signs There is most danger when the epiglottis and larynx are involved for edema and inflammatory swelling may cause complete *closure and death from suffocation* Ulceration may destroy the laryngeal cartilages

Syphilis of the lung has long been considered a rare disease but evidence is now accumulating which shows that it is more frequent than has been generally supposed Cough with expectoration (sometimes bloody), loss of weight and a variable fever —symptoms which are identical with those of pulmonary tuberculosis—*are the usual* manifestations The physical signs except perhaps for their location also suggest phthisis *Roentgenologic* signs are sometimes fairly characteristic and can be recognized by the fact that the process is largely limited *to* one part of one lung usually the middle or lower portion With proper treatment the prognosis is excellent

THE DIGESTIVE ORGANS —(A) THE ESOPHAGUS —Syphilis of the esophagus is rare and usually represents extension of the infection *from some neighboring structure*

(B) STOMACH —Early in the disease functional gastric disturbances are frequent The patient *complains of lack of appetite and of* a sense of pressure in the epigastrium At times there is regurgitation of food A large *percentage of patients have lowered acidity* perhaps anacidity or achylia Little is known of the actual gastric pathology at this stage and it has been suggested that much of the distress and disturbance of function is due to disease of the vagus nerve Although involvement of the stomach may occur at any time after invasion by the spirochete becomes general outspoken syphilis of this organ is usually a late manifestation of the disease The existence of syphilis of the *stom*ach as an etiologic entity has been questioned but this was answered by Harris *and Morgan when they recovered* the organism from the gastric lesion and a regional lymph node Eusterman describes three types of cases (1) The most frequent is the type in which epigastric pain comes on immediately after eating and is made proportionately worse by an increase in the solidity of the food or in the amount of fluid taken The capacity of the stomach becomes greatly reduced vomiting is frequent and partial starvation results *Dumb*bell and high hour glass stomachs are seen Sixty three per cent of the cases were of *this group (2) The pseudo cancer type* was represented by 15 per cent of the cases There is a gradual onset with mild pains one half hour or more after eating relief obtained from food and alkalis is inconstant and incomplete (3) The ulcer type with typical ' pain food ease ' was encountered in 22 per cent of the cases

(C) THE INTESTINES —Syphilis of the intestines is rare In early syphilis a diarrhea *occasionally occurs which* if untreated may become chronic This symptom is encountered more frequently however in the later stages of the disease Such catarrhal diarrhea is particularly severe in cachectic individuals Gummata occasionally form in the intestinal wall they may break down into ulcers which in healing produce circular *scars and* stenosis Gummas may also appear in the rectum

but according to Ault stricture of the rectum due to syphilis is rare The picture revealed by the proctoscope is not typical

(D) THE LIVER —Invasion of the liver is frequent and symptoms referable to this organ are encountered often both early and late The mild icterus suggestive of catarrhal jaundice which occasionally appears either before or during the efflorescence may be an extension of the disease from the duodenum or a true exanthem of the bile passages The presence of jaundice with or without other symptoms in a patient with early untreated syphilis usually points to acute benign syphilitic hepatitis which disease according to Waugh clears up rapidly (usually with a mild Herxheimer s reaction) when small doses of arsphenamine are given There may also be enlargement of the spleen and fever A rapidly fatal disease of the liver apparently identical with acute yellow atrophy may develop within a year after infection

The late manifestations of syphilis of the liver are the formation of gummas and chronic interstitial inflammation either alone or together Gummas may be miliary (often multiple) or they may reach the size of large tumors They usually begin in the immediate neighborhood of a blood vessel which they eventually destroy Fibrous tissue with scars usually results but other retrogressive changes may lead to localized fatty or amyloid degeneration As a rule gummas of the liver do not break down but when they do an irregular perplexing fever often ensues

Chronic interstitial hepatitis begins with a cellular infiltration around the blood vessels which extends and leads finally to the production of thick fibrous tissue Gradually there develops a cirrhosis of the liver in which the parenchyma is replaced by this newly formed connective tissue Bands of tissue often divide and distort the liver so that it assumes an abnormal often bizarre shape which serves to distinguish this form of cirrhosis from the ordinary type described by Laennec although the latter disease may sometimes occur as the result of long continued syphilis alone or in association with alcoholism This type of cirrhosis develops slowly over a period of years It may exist for a long time without producing symptoms although, as a rule definite signs are present The liver is often nodular It may be larger than normal or, because of the constricting bands, may undergo atrophy in one part and hypertrophy in another Ascites hematemesis and other signs of portal obstruction are evident Jaundice and albuminuria are usually present as well as severe pain and a low grade fever With gummas alone the prognosis is relatively good, but with chronic interstitial inflammatory changes treatment avails little

(E) THE PANCREAS —Indurative pancreatitis occasionally occurs as a late syphilitic process The parenchyma is replaced by connective tissue and the organ becomes hard usually larger than normal and in thin individuals can occasionally be palpated This type of interstitial pancreatitis is however rarely recognized during life Gummata also occur Syphilis of the pancreas is often associated with syphilis of the liver Syphilitic diabetes mellitus is rare Joslin reports that sixteen out of 1000 diabetics gave a positive Wassermann reaction

THE KIDNEYS AND URINARY TRACT —Mild albuminuria with or without casts is a frequent accompaniment of early syphilis and is usually associated with no other symptoms of renal involvement During this period there may develop however a true acute syphilitic nephritis with edema and other symptoms identical with those of the usual glomerular nephritis The treponema and not mercury or arsenic as is sometimes suggested is probably the causative agent A little later there occasionally appears a degenerative disease identical in its clinical features with nephrosis Its onset may be rapid or insidious The disturbance is distinguished by marked edema pallor prostration headaches and scanty excretion of urine containing much albumin and a sediment composed in part of degenerated kidney epithelium hyaline and granular casts and certain characteristic lipoid bodies These lipoid bodies appear in the urinary sediment as small droplets which when viewed in a polarized light seem to be divided by a black cross into four highly refractile sections They serve to distinguish this disease from the nephritis of a similar character which occasionally follows the ex

cessive use of mercury The prognosis is good under treatment

In its later stages, syphilis sometimes gives rise to a nephrosclerosis which may follow the disease just described or develop gradually without previous symptoms It has the following distinctive characteristics there is often no elevation of blood pressure, polyuria is usually absent, the water concentration test shows little impairment of the ability of the kidneys to excrete nitrogen and salts and there is moderate albuminuria with an abundance of hyaline casts and occasionally lipoid bodies With treatment the outlook for arresting the disease is good

Gummata occasionally appear in the kidneys, but cannot be recognized during life unless they reach the size of great tumors

The urinary bladder sometimes gives trouble in early syphilis It presents the symptoms and cystoscopic appearances of chronic cystitis or tuberculous cystitis In late syphilis ulcers may appear as the result of broken down gummas

THE TESTICLES AND OVARIES —Animal experiments have shown that the treponema grows with especial ease in the testicle a fact corroborated by clinical experience *The semen in early syphilis may contain* treponemas, even when there is no clinical evidence of testicular involvement Orchitis, a fairly frequent and characteristic manifestation of syphilis may occur early although it appears as a rule two or three years after primary infection It is usually double The testicle is swollen hard and rarely painful The epididymis is involved *in only about one half the cases* This chronic interstitial inflammatory process may destroy the parenchyma and produce finally a small sclerosed testicle but only certain parts of the organ may be involved and some parenchyma left to function Syphilitic orchitis may be confused with gonorrhea tuberculosis *or carcinoma* Pain fever and involvement of the epididymis are characteristic of *gonorrhea* pain degenerative changes and the presence of *tubercle bacilli* in the urine characterize *tuberculosis* while *carcinoma* grows faster is usually unilateral and has an even contour Gummata with the eventful formation of fistulae occasionally involve the testicle

Little is known of syphilis of the ovary It probably leads to menstrual disturbances and eventually to amenorrhea and sterility

OTHER ORGANS OF INTERNAL SECRETION — The *thyroid gland* is occasionally enlarged in early syphilis most often when the disease has been untreated Late in the disease it may undergo a chronic inflammatory change which results in fibrosis and may cause symptoms of pressure or lead perhaps to myxedema

Syphilitic involvement of the *hypophysis* and *its neighboring tissues can give rise* to *diabetes insipidus* or to the endocrine disturbance known as *dystrophia adiposogenitalis* Syphilis may destroy the *adrenals* and induce Addison s disease

THE NERVOUS SYSTEM —Syphilis of the central nervous system is difficult to classify because from neither an anatomic nor a clinical standpoint are the several types clearly defined They occur together overlap and merge into one another For purposes of description the following grouping is the best

1 Meningeal syphilis
2 Cerebrospinal syphilis
   (a) Vascular
   (b) Parenchymatous

(A) MENINGEAL SYPHILIS —The *meninges* are involved early and with great constancy Estimates as to the frequency of such disturbances in early syphilis which are based upon examination of the spinal fluid vary from 50 to 100 per cent Dreyfus found changes in the spinal fluid of 80 per cent of patients with syphilis The vast majority of such patients give no clinical evidence of meningitis yet the character of the cells in the lumbar fluid shows that a true meningitis though of low degree exists The spinal fluid undergoes some elevation of pressure there is pleocytosis chiefly of mononuclear cells with occasional polynuclear and plasma cells and the globulin content is markedly increased The Wassermann reaction of the spinal fluid may be negative at this stage although that of the blood is positive These signs of meningeal involvement disappear *quickly if treatment is thorough* but they may remain for a long time in poorly treated or neglected patients Their chief importance lies in the fact that if they are dis

regarded a small percentage of the subjects will years later, develop tabes or paresis

Less often there occurs a syphilitic meningitis with outspoken clinical signs This disorder may appear very early even before any other general manifestations are evident but it usually develops simultaneously with the skin symptoms during the first generalized invasion of treponemas There is manifest inflammation of the meninges with connective tissue proliferation and the formation of new granulation tissue which dips into the brain substance and thus establishes a true meningo-encephalitis As usual there is involvement of the smaller arteries and veins The meningeal lesions are not evenly distributed but are confined to more or less restricted areas Basal meningitis which involves chiefly the region of the optic chiasma and the space between the peduncles is the most frequent form The coverings of the cord are often involved in the region of the posterior columns (tabes) The symptoms depend largely upon the location of the inflammatory process The preponderance of basal meningitis accounts for the frequency of syphilitic paralysis of the cranial nerves Involvement of the region of the hypophysis may lead to *diabetes insipidus* If the cortex is attacked psychic disturbances headaches vomiting aphasia and perhaps jacksonian epilepsy may follow There may be delirium coma or convulsions The onset of epilepsy in a patient thirty or more years of age is always suggestive of cerebral syphilis With early sustained treatment the prognosis of early syphilitic meningitis is good

Syphilis of the dura mater is usually an extension of the disease from the other membranes or from the bone Two types have been distinguished a *pachymeningitis haemorrhagica interna* and a *pachymeningitis hypertrophica* Both are serious

(B) The Brain and Cord.—Syphilis of the brain most often appears as part of a syphilitic meningitis—meningo encephalitis *Involvement of the blood vessels* as repeatedly stated is a prominent feature in all syphilitic pathology especially here for it is most often through the vessels and the accompanying perivascular infiltration that the disease is spread to the brain The changes are essentially interstitial and affect the nervous tissue only indirectly At the same time treponemas may penetrate into the brain substance and, on reaching the nerves themselves give rise to a true parenchymatous cerebrospinal syphilis Luetic *endarteritis obliterans* often interferes with the cerebral circulation and leads to softening of the brain These processes seem to have a preference for the interpeduncular space at the base of the brain and for certain cortical areas Both may be involved With involvement of the base disturbance of the cranial nerves is frequent The optic nerve the extrinsic nerves of the eye and the auditory nerve are most often affected It is said that an optic neuritis is much more common in early syphilis than is ordinarily thought With syphilis of the cortex there may be headache psychic disturbances jacksonian epilepsy and various motor symptoms While the several forms of cerebrospinal syphilis just described usually occur early in the disease often in the first year they may also appear late As a rule however the late manifestations of this type are due to gummata or usually to combined gummatous and fibrous processes which arise in the meninges and extend along the vessels to the brain or cord The symptoms depend upon the location of the tumor

The prognosis of these interstitial processes is good if treatment is early and energetic This is not true however when the treponema has extensively invaded the brain substance and is not within easy reach of bismuth and arsenic When the treponemas invade the nerves themselves degeneration of these structures follows and irreparable damage is done

If such invasion is extensive it must be called *parenchymatous cerebrospinal syphilis* Outstanding examples of this group are paresis and tabes dorsalis The symptoms of the parenchymatous forms are similar to those of the meningeal and vascular forms but vary of course according to the location of the process There are three features which are said to characterize the symptoms of cerebrospinal syphilis (*a*) their extreme variability and disappearance with recurrence at short intervals (*b*) their multiplicity and involvement of widely

separate areas, and (*c*) their association with structures at the base of the brain

Dementia paralytica and tabes dorsalis are placed in a category of their own because, being a late effect of the localization of the treponema in the parenchyma of the brain or cord, each presents a fairly well-defined symptom complex. The two are often combined, with varying emphasis on the one or the other, and tabes is today sometimes looked upon merely as a part of the exceedingly variable syndrome of neurosyphilis, but for purposes of description each can be regarded as definite clinical entity. These will be discussed elsewhere. (See *Syphilis of the Central Nervous System*.)

Inadequate or irregular treatment is an important factor in the development of *syphilis of the central nervous system*. This was clearly shown in the studies of Wile and his associates, and in the report of O'Leary.

THE EYE AND THE EAR.—The eye is frequently involved in syphilis and sometimes offers the only recognizable symptom. A plastic *iritis* often occurs early, and *iridocyclitis* perhaps a little later. An especially severe form of iritis, the *iritis papulosa*, may appear relatively early or as a late manifestation. Retinitis develops in late syphilis; the retinal vessels show characteristic changes and hemorrhages may occur. The optic nerve is not infrequently congested in early syphilis, while in the late disease there is often an optic neuritis or neuroretinitis which if untreated may lead to optic atrophy. The apparent hopelessness of this last is seen in the studies of Lehrfeld and Gross. Of 570 patients with optic atrophy who received no treatment 74.9 per cent were blind in less than three years and all were blind at the end of five years; of those who received the most aggressive treatment, including fever therapy and subdural injections, 28 per cent were blind in less than three years and all were blind at the end of eight years.

Otitis media is often an early manifestation of syphilis. It differs but little from other forms of otitis media except in the unusually rapid loss of hearing, the pains in the bone, and the fact that the disease is usually bilateral. In late syphilis the process may lead to destruction of the internal ear. Deafness follows involvement of the auditory nerve.

OTHER INDEFINITE LATE MANIFESTATIONS.—Certain other indefinite symptoms of a general nature are prone to occur in late syphilis. A low grade fever, otherwise difficult to explain, should always excite a suspicion of syphilis. The fever of pneumonia and of typhoid fever has been known to continue long after apparent recovery and then promptly subside as soon as a positive Wassermann reaction was discovered and antisyphilitic treatment instituted. The emotional instability which we call "neurasthenia" occasionally occurs in late syphilis without other signs of disease. An indefinite state of ill health with malaise, anemia, and lack of initiative may also be the result of so called "latent syphilis."

Syphilis in the pregnant woman, no matter what the stage of pregnancy, demands energetic treatment. The Wassermann test should be done twice during every pregnancy, at the third and eighth months. If treatment is begun before the fifth month and is sustained, the chances are good that a healthy child will be born. The pregnant syphilitic woman tolerates antisyphilitic treatment well and the outcome is favorable in direct proportion to the amount of such treatment she has received. The fetus responds to arsenic in the usual manner.

Congenital syphilis is transmitted only through the mother. If the disease originally comes from the father, he infects the mother and she, through the placenta, infects her offspring. The duration of the infection in the parent has an important influence upon the likelihood of transmission. Fournier showed that the disease is transmitted usually during the first three years after infection. The danger then gradually lessens, so that five to ten years after the initial lesion syphilis is as a rule no longer transferable by the father. The mother, however, may even after twenty years infect her child. According to estimates quoted by Whipple and Dunham, of 683,000 syphilitic persons under observation in the United States more than 60,000 acquired the disease from the parent, this in spite of the fact that, as was shown in the Cooperative Clinical Studies, congenital syphilis is a preventable disease.

The *symptomatology of congenital syph*

ilis does not differ materially from that of the acquired disease except that there is no primary sore and the late manifestations appear much earlier sometimes indeed simultaneously with the usual early symptoms Those children who at birth show outspoken evidence of syphilis and who usually die within the first few weeks of life have a true treponema septicemia This is manifested by the bullous eruption of the skin the fissures about the angles of the mouth and nose, the characteristic nasal discharge to which the name *snuffles* has been given the enlargement of the spleen and liver the bony changes about the joints the poor state of nutrition and the faulty development. The congenitally syphilitic children who are conceived at a later period of the parental disease and who at first show no recognizable symptoms a little later usually appear unmistakably syphilitic. *Snuffles* is one of the most constant symptoms *Eruptions* macular or papular appear upon the skin most often on the buttocks or the face the macules are of a coppery brown color with well-defined edges Instead of this type of rash there may be a mere erythema or an eczema The papules tend to become confluent and to cover large areas especially on the hands and feet and around the mouth In the severe cases bullae appear which burst and may produce large sores The skin and mucous membranes of the lips may undergo a peculiar diffuse infiltration called *cheilitis diffusa* Fissures appear at the corners of the mouth when these are deep and ulcerated they are called *rhagades* In healing they leave linear radiating scars which are peculiarly characteristic of congenital syphilis Syphilitic *onychia* is common and the hair may fall out These children are apt to be unusually restless at night and are said to have a peculiar harsh high pitched cry

Teeth—*Hutchinson's teeth* provide the most characteristic feature of congenital syphilis The central incisors of the permanent teeth most often the upper are notched on their free borders as if a half moon shaped piece had been chipped out moreover they are usually peg-shaped that is smaller at the free end than at the gums Additional defects involving peculiarities of form size and spacing of the teeth are seen but these last are common to other states of malnutrition and are not peculiar to syphilis

The Blood—Anemia is frequent Josephs states that severe anemia appearing during the first three months after the neonatal period is always suggestive of congenital syphilis

The Digestive Organs—The liver is often extensively involved and is usually enlarged It is subject to the same lesions observed in acquired syphilis *Diffuse hepatitis* may develop about the time of puberty and lead to cirrhosis of the liver The *spleen* also is often enlarged Both the *pancreas* and the *kidneys* are subject to chronic interstitial inflammation in late congenital syphilis and both may be retarded in their development

Bones—Characteristic of congenital syphilis is an *osteochondritis* which attacks the centers of ossification between the shaft and epiphyses of the long bones The normally thin zone of calcification becomes very much widened and irregular a condition easily recognized in the radiogram Swelling and pain in this area are the chief symptoms The lower end of the femur is the region most often attacked

The Nervous System—In congenital syphilis the central nervous system is subject to the same changes as the acquired form In addition the retarded and abnormal cerebral development may lead to epilepsy hydrocephalus or idiocy It is said that juvenile dementia paralytica develops in about 1 per cent of all patients with congenital syphilis

The Eye and the Ear—Later in the disease often in adult life there is an *inflammation of the cornea* an interstitial keratitis which is seldom seen in the acquired disease but is especially characteristic of congenital syphilis It may occur at any time although the onset is most often between the ages of six and fifteen years Of 247 congenitally syphilitic children studied by Lennarson and Jeans 43 per cent of those more than two years of age had interstitial keratitis Of 1010 patients with late congenital syphilis studied by the Cooperative Clinical Group this condition was the principal initial diagnosis in one third of the cases Untreated the disease leads to cloudiness of the cornea and frequently to blindness Optic

neuritis and chorioretinitis also occur Optic atrophy is less frequent Involvement of the ear is common and may lead to deafness

The *recognition* of congenital syphilis is not always easy, the apparently normal infant of a syphilitic mother may have the disease The presence of the well known triad Hutchinson's teeth interstitial keratitis and deafness merely tells of irreparable damage already done The diagnosis must be made earlier and for this purpose correlation of many factors is often necessary the appearance of the infant, the demonstration of the disease in the parents serologic tests of both infant and cord the roentgenologic appearances of the bones and the finding of spirochetes in the placenta For testing the blood of suspected infants Faber and Block advise quantitative rather than qualitative methods

Diagnosis—The chancre can often though not invariably be distinguished from the chancroidal ulcer by the following characteristics the former has a definite period of incubation while the latter has not the typical chancre presents a clean slightly elevated circumscribed ulcer the edges of which are not excavated the chancroidal ulcer exudes an abundant pus has an inflammatory areola and is elevated with undermined edges the former rests upon a hard base of almost cartilaginous consistency while the latter is soft The only sure diagnostic criterion is the finding of the treponema This is not difficult in a dark field preparation made of serum expressed from a relatively fresh untreated chancre or aspirated from a neighboring lymph node One group of experienced workers report positive dark field examinations in 94 per cent of seronegative primary syphilis and in 90 per cent of the genital lesions of secondary syphilis Failure to find the organism however should not be accepted as final

Later in the disease the history may be of importance particularly if it tells of a primary sore or secondary rash or in a woman of repeated miscarriages Experience has taught, however that a negative history *should* be accorded little consideration The physical examination may uncover significant findings such as the scar of a chancre evidences of old skin lesions persistent enlargement of the lymph nodes or bony changes such as the distinctive saber shin

Serum Reactions—Of great importance in the diagnosis of syphilis and in the evaluation of treatment are the Wassermann complement fixation reaction and the several flocculation tests As a rule the reaction is not immediately positive and cannot be obtained until about the time the so called secondary symptoms develop usually the eighth or ninth week after infection After this a positive Wassermann reaction is the most constant of all signs of syphilis and in the vast majority of cases it remains positive until influenced by treatment With the rarest exceptions it always indicates active syphilis—active even though it may not produce symptoms In addition this reaction serves as an excellent guide to treatment, for it has been demonstrated that the majority of patients who are adequately treated experience a reversal of a hitherto positive Wassermann reaction within a year usually within six months A weakly positive test (1 plus) occurring after a series of negative reactions in early syphilis warns of approaching relapse, the spinal fluid should immediately be examined

The flocculation tests (notably of Kline or Kahn) have come to enjoy equal favor with the complement fixation test The American Serological Conference concluded that for both the blood and the spinal fluid the clinician can place equal value upon either test efficiently performed This conference reported approximately 100 per cent of positive reactions in untreated secondary syphilis and 63 to 84 per cent of positive reactions in late syphilis with varying treatment It was found that frequently in leprosy and sometimes in malaria, a false positive reaction was obtained

Seroresistance (Wassermann fastness) can be said to exist in early syphilis when at the end of six months of continuous treatment the serum reaction is still positive According to Moore and Padget this can be regarded as a manifestation of persistent foci of organisms or of progressive activity and as presumptive evidence that treatment has been inadequate or irregular in a *large* proportion of such cases the spinal fluid will reveal involvement of the neural axis In late syphilis seroresistance as indicated by a

positive reaction at the end of a year of continuous treatment has a different significance According to authors just quoted it can be regarded as an integral part of the manifestations of many late forms of the disease or as evidence of the persistence of well established immunity

The *spinal fluid* should be examined invariably in both early and late syphilis Asymptomatic neurosyphilis is of frequent occurrence and its prompt recognition may prevent the later development of serious trouble In spite of its lack of specificity the increased cell count is in the presence of a syphilitic infection a finding of the utmost importance as an index of involvement of the nervous system early in the course of the disease' Patients so characterized are peculiarly disposed to the subsequent development of the more serious forms of neurosyphilis At any stage of the disease a positive Wassermann reaction in the spinal fluid indicates active cerebrospinal syphilis and if the reaction remains positive long the patient is fortunate if he escapes paresis or tabes An increase in the globulin of the spinal fluid and a positive colloidal gold reaction with its characteristic curve are both of diagnostic significance

Prognosis—Syphilis can be cured Much depends however upon the promptness with which treatment is instituted and the fidelity with which it is continued The ease with *which cure can be accomplished is in inverse* ratio to the age of the infection If begun within the first few weeks or months after infection sustained treatment usually means an early and assured cure After two or three years cure is more difficult while in cases of ten or twenty years duration complete eradication of the infection is extremely difficult and often impossible The lesions of early syphilis usually heal without causing loss of function but in late syphilis with deep seated lesions and extensive destruction of parenchyma there can never be complete restoration of function Chronic syphilis is refractory to treatment because of the persistence of pathologic processes beyond the reach of medication For the same reason congenital syphilis does not yield readily to therapeutic measures

Prophylaxis—The sure way to escape syphilis is to avoid exposure Immediately after exposure the disease can generally be prevented by the prompt and thorough application of calomel ointment to the contaminated parts (calomel 3 parts, lanolin 1 part benzoinated lard 2 parts) Spirochetes placed on the intact genital mucosa of rabbits have been found after one hour to be buried within the crypts and after two hours to have penetrated the deeper tissues To be effective therefore chemical prophylaxis should be applied early preferably within an hour after exposure

Treatment—*General*—The patient himself as well as the disease requires treatment If he has fever he should be kept in bed and other symptoms of a general or specific nature must be combated with appropriate remedies Great attention should be paid to hygiene Alcohol should be avoided worry and overwork prevented as far as possible and sufficient sleep and recreation specifically prescribed A simple rational diet should be ordered The teeth should receive the best of care Repeated examinations of the urine and frequent physical examinations should be made Every patient no matter what the circumstances should in the beginning be told of the nature of his infection and should be warned of the tediousness of successful treatment The physician must have his confidence and his firm allegiance Otherwise the necessity for treatment will not be sufficiently appre*ciated and failure may result If the patient* is married the wife or husband as the case may be must be informed of the situation and due precautions taken to prevent transmission of the disease

Specific—Unlike many other infections syphilis is not self limited If the patient is to escape its harmful effects thorough continuous treatment is necessary True a few patients with early syphilis get well following meager therapy but this is exceptional To offer any assurance of success treatment should conform to the following specifications (1) it should be instituted early (2) it should be sustained and without interruption and (3) it should be long continued

As soon as the diagnosis is made even though the disease is yet in the seronegative stage treatment should begin for the longer this is delayed the more difficult it is to ef

fect a cure The "Cooperative Clinical Studies" indicated that treatment begun in the primary though seronegative, stage possesses a superiority of curative outlook of about one third over that begun in the secondary stage This superiority of early treatment becomes still more striking as the later stages are approached This is well illustrated in the studies of syphilis of the heart and aorta by Moore and his coworkers who conclude that adequate treatment for early syphilis almost certainly protects the patient against subsequent cardiovascular syphilis

Continuous treatment is necessary The 'Cooperative Studies just quoted demonstrated that uninterrupted medication is infinitely superior to the intermittent treatment in vogue in the past Among cases treated with arsphenamine alone, the continuous method secured the reversal of the blood Wassermann reaction by the end of a year in 91.2 per cent whereas the intermittent scheme of treatment with arsphenamine alone and rest intervals of a month or more secured only 58 5 per cent of reversals, and irregular treatment with arsphenamine alone secured only 9 3 per cent of Wassermann reversals to negative within a year Essentially the same proportions appear in discussing the serologic results with arsphenamine and heavy metal It is believed that the vast majority of failures in the treatment of syphilis notably in its early stages are due to the rest interval rather than to any peculiarity of the infecting organism or of the patient

Treatment should be prolonged It has been demonstrated that prolongation of continuous treatment for more than a year enhances enormously the patient s chances for complete recovery Much longer periods are often necessary especially if treatment is begun late

Three groups of drugs are of value in the treatment of syphilis the arsphenamines certain heavy metals (bismuth and mercury) and the iodides The members of the first two groups are spirocheticidal and tend directly to eradicate the infection while those of the last group promote the resorption and removal of the late manifestations of the disease The opinion has recently been expressed however that the iodides are not as indispensable as was formerly thought, and that the same effects are possibly better accomplished by arsenical or bismuth compounds

Arsphenamine and neoarsphenamine, directly or after conversion in vivo to some related compound are both strongly spirocheticidal in the earlier stages these drugs cause the rapid disappearance of the syphilitic manifestations Both are equally effective in the late stages also and one of them, with the occasional substitution of bismuth should be used throughout the course of treatment Both are administered intravenously They deteriorate when exposed to the air and each ampule therefore should be examined for leaks before use Only freshly distilled water is to be employed for preparing the solution, it should be administered with absolute asepsis and in sufficient dilution In the case of arsphenamine the neutralization of the dissolved salt should be exact and to permit completion of the chemical reactions the solution should stand a few minutes preferably thirty minutes and not longer than three hours before use In the case of neoarsphenamine however the solution should be administered immediately after preparation The dose of arsphenamine is 0 2 to 0 6 Gm that of neoarsphenamine 0 2 to 0 9 Gm Arsphenamine is the more potent drug of the two and is to be preferred but neoarsphenamine because of its ease of preparation is much more widely used For those cases in which intramuscular injections are necessary *sulfarsphenamine* is best The drug should be dissolved in 1 to 2 cc of sterile distilled water and injected at weekly intervals into alternate buttocks until ten doses have been given

Mapharsen a cleavage product of arsphenamine is a potent antisyphilitic agent and has the advantage of producing fewer reactions Reports tell of satisfactory administration of this drug to patients who had previously experienced gastro intestinal upsets nitritoid reactions and other untoward effects from the arsphenamines The recommended course consists of twelve intravenous injections of 0 03 to 0 06 Gm each given at five day intervals

Tryparsamide is of value in the treatment of cerebrospinal syphilis, but is not recom

mended for other forms of the disease It should never be given unless facilities are available for examination of the fundi and visual fields by a competent ophthalmologist It is administered in doses of 1 to 3 Gm

Bismuth is superior to mercury in therapeutic effectiveness It should be used in conjunction with the arsphenamines or their derivative marpharsen An insoluble compound such as bismuth subsalicylate suspended in oil (0.2 Gm of the metal) injected intramuscularly at weekly intervals is generally preferred Water soluble compounds such as iodobismitol may be given for their quicker effect when the arsphenamines are contraindicated but they have the distinct disadvantage of requiring more frequent administration two to three times a week Sobisminol in the form of Sobisminol Mass is effective when given orally in capsules containing each 150 mg of metallic bismuth four to six capsules daily Only an exceptionally intelligent person however will continue persistently and faithfully to take oral medication for the prescribed period The subsalicylate given intramuscularly at weekly intervals is best

Mercury is seldom used today because it is less effective than bismuth When used the inunction method is best The dangers incident to its irregular absorption and accumulation must always be kept in mind

Potassium (or *sodium*) iodide is believed to be of value in all except the very earliest infections Apparently the iodides have no spirocheticidal effect but they facilitate the healing of gummas and other destructive lesions of late syphilis The drug should be given by mouth in doses of 10 to 40 grains daily

The Untoward Effects of Treatment— Arsphenamine dermatitis an exceedingly disastrous complication is much more likely to occur during the first course of treatment and is more frequent in patients who are receiving simultaneous arsenical and heavy metal therapy Statistics indicate that patients who are treated by the well established routine method are less susceptible than those who are treated by individualized methods Epstein states that the incidence of exfoliative dermatitis would be greatly reduced if before treatment with arsphenamine all patients with late syphilis were prepared by treatment with heavy metal Itching of the skin during the period of treatment may be a warning of approaching dermatitis and should be looked upon as a symptom of grave significance, it should suggest the abandonment of the arsphenamines Dermatitis is always a contraindication to the use of these drugs Jaundice even acute yellow atrophy of the liver and serious damage to the kidneys and bone marrow may follow arsphenamine therapy The nitritoid crisis is an immediate reaction which is accompanied by a flushing of the neck and face injection of the conjunctiva choking sensation palpitation backache and perhaps edema of the lips and tongue with occasional collapse Idiosyncrasy of the patient or perhaps faulty technic is responsible Adrenalin given before treatment may prevent this crisis Patients with cardiovascular syphilis may experience sudden collapse and even die during arsphenamine treatment a catastrophe which can usually be prevented by the restriction of medication to very small doses or the substitution of neoarsphenamine (0 1 to 0.3 Gm) for the older drug

The Herxheimer reaction which may follow a first injection of arsphenamine is a 'flare up of an old syphilitic lesion and is of serious significance only when a vital structure is involved

To prevent such reactions the Cooperative Clinical Group offers the following suggestions (1) Before beginning treatment search for a history of idiosyncrasy allergic tendencies skin irritability (especially eczema and seborrhea) focal and intercurrent infections liver damage and pregnancy (2) Before each treatment inquire regarding (*a*) gastro intestinal reactions and (*b*) the condition of teeth and gums and examine at least the eyes (jaundice) face (dermatitis) mouth (salivation purpura) flexures of the elbows (dermatitis) wrists and ankles (purpura) Take the temperature (3) Make the first dose of any drug not more than half of full dose (4) Pull back on syringe pistons (*a*) in intravenous injections to be sure of entry in vein and (*b*) in intramuscular injections to be certain a deep vessel has not been entered (5) Inject intramuscularly into the inner angle of the upper outer quadrant of the buttock and massage long and

A SCHEME OF TREATMENT FOR EARLY SYPHILIS (MOORE AND ASSOCIATES MANAGEMENT OF SYPHILIS IN GENERAL PRACTICE SUPPLEMENT No 6 TO VENEREAL DISEASE INFORMATION U S PUBLIC HEALTH SERVICE)

DAY* OR WEEK	ARSPHENAMINE GM	INTERIM TREATMENT	BLOOD WASSERMANN REACTION	REMARKS
Day				
1	0 3–0 6		1	Arsphenamine dosage for first 2 injections at level of 0 1 Gm for each 25 pounds of body weight Average subsequent dosage 0 4 Gm men 0 3 Gm women In average patient all lesions heal rapidly and blood serologic test becomes negative during first course If arsphenamine cannot be used substitute 8 to 10 doses 0 3 Gm silver arsphenamine or 10 to 12 doses 0 6 Gm neoarsphenamine This applies also to subsequent courses
5	0 3–0 6			
10	0 3–0 6			
Week				
3	0 4			
4	0 4			
5	0 4			
6	0 4			
7	0 4			
8		Bismuth 4 doses 0 2 Gm and KI or Ung Hg and KI		
9				
10			1	If mercury is used note overlap of one week at end of first and start of second arsphenamine courses
11				At this point a few days without treatment may be dangerous (neurorecurrence)
12	0 4		1	Arsphenamine starts bismuth stops Watch for provocative Wassermann reaction after first dose of arsphenamine
13	0 4			
14	0 4			Try to prevent lapses in treatment especially at this early stage
15	0 4			
16	0 4			
17	0 4		1	
18–23		Bismuth 6 doses or Ung Hg and KI		*Bismuth is better than mercury* Use it if possible Examine cerebrospinal fluid at about this time
24	0 4			
25	0 4			
26	0 4

28	0 4			
29	0 4			
30–37		Bismuth 8 doses or Hg and KI		
38	0 4		1	
39	0 4			
40	0 4			
41	0 4			
42	0 4			
43	0 4		1	Patients with seronegative primary syphilis may cease treatment here if blood serologic test has always been negative
44–53		Bismuth 10 doses or Ung Hg and KI		Note that bismuth or mercury courses are now gradually getting longer—4 6 8 and now 10 weeks
54	0 4		1	The average seropositive primary or early secondary patient should have at least 5 courses of arsphenamine
55	0 4			
56	0 4			
57	0 4			
58	0 4			
59	0 4		1	
60–69		Bismuth 10 doses or Ung Hg and KI		It is safer to finish treatment with bismuth or mercury rather than with arsphenamine
70–122		Probation no treatment	6–12	Blood serologic test every month if possible at least every other month
123	Complete physical and neurologic examination spinal puncture and if possible fluoroscopic examination of cardiovascular stripe. Thereafter yearly physical examinations blood serologic test every 6 to 12 months If the 2 spinal fluid examinations above are negative this need not be repeated later			

well (6) Inject intravenous solutions slowly through a small needle not faster than 0 1 Gm per minute for arsphenamine (7) Permit only a light meal before and after an arsenical and prescribe a mild cathartic the morning after (8) Examine urine biweekly and (9) give calcium freely With these suggestions is included not only the admonition that alcohol be interdicted but also the advice that carbohydrates be restricted and proteins and fats permitted in liberal amounts I doubt the wisdom of restricting the carbohydrates Animal experiment would indicate the advisability of giving large doses of ascorbic acid say 50 to 100 mg daily

Plan of Treatment —*Early syphilis* should be treated from the very beginning with arsphenamine and bismuth which should be continued without interruption (see accompanying schedule) Not less than twenty and seldom more than thirty injections of arsphenamine are required No rest period should be permitted until a full year of treatment has been completed Furthermore treatment should always be continued for one year after the blood and spinal fluid Wassermann tests have become negative and remained so

Blood tests should be made at the beginning and end of each arsphenamine course and the spinal fluid should be examined before the arsphenamine treatment is discontinued A negative blood test should not be permitted to interfere with the previously arranged schedule

Latent and *late syphilis* cannot be treated in quite such a routine manner because many circumstances related to the patient s condition demand individualization of the treatment The routine above outlined however is generally applicable Intermittent treatment with rest periods is not so objectionable in late as in early syphilis Treatment should not be too intensive lest damage be done to important structures The urine should be watched and great caution should be observed in giving the arsphenamine in syphilis of the liver In cardiovascular syphilis neoarsphenamine is the drug of choice but it should be given in very small doses Bismuth also should be given If aortic insufficiency is present prolonged treatment with this metal should precede the use of neoarsphenamine if there is cardiac failure the arsphenamine should be withheld until competency has been restored If there is early involvement of the central nervous system arsphenamine and bismuth should be given the former being administered in an intensive manner and at intervals of five rather than seven days later tryparsamide under proper control and perhaps fever therapy should also be given Visceral syphilis demands the arsphenamine and bismuth therapy described above plus liberal amounts of the iodides In general it can be said that treatment of late syphilis should be less intensive than that of early syphilis and without regard for the Wassermann reaction continued over a period of two years

Massive arsenotherapy, designed to cure syphilis in a few days is still an experimental procedure but it apparently holds promise The slow intravenous drip method first proposed by Hyman and his co workers has been slightly revised and the procedure used today is to give a total of 1200 mg (1 2 Gm) of Mapharsen throughout a period of five days This amount of the drug is administered by one of three methods (*a*) by slow intravenous drip in which 2000 cc of solution is given continuously each day for periods of seven to ten hours each (*b*) by rapid intravenous drip in which 1000 cc of solution is given continuously each day in periods of one to three hours each and (*c*) by multiple daily injections of small amounts of solution given with a syringe A recent progress report states that the treatment is effective and that the toxic manifestations are mild and infrequent with the exception of toxic encephalopathy the incidence of which is higher with all intensive methods than with the standard methods of treatment Other less highly intensive methods designed to shorten the standard treatment to a period of a few weeks or months are also being studied Further reports will be looked for with interest

Even more startling is the proposed one day cure Artificial fever (106° F) is maintained for about ten hours and during this period the patient is given arsenotherapy by multiple injections Satisfactory results have been reported but the efficacy of the method and its safety is still under investigation

The treatment of congenital syphilis

should not be too aggressive in the beginning When it is recognized early, medication should begin with the administration of mercury with chalk 0 015 Gm to 0 03 Gm (¼ to ½ grain) three times daily for one or two weeks or with injections of bismuth *subsalicylate in doses of 0 001 Gm* per kilogram given at weekly intervals until three doses have been given Then sulfarsphenamine, beginning with 0 005 Gm per kilogram gradually increased to 0 01 Gm per kilogram should be given intramuscularly at weekly intervals for ten weeks Following this the child should be given forty to fifty intramuscular injections each of sulfarsphenamine and bismuth arranged in alternating courses each of ten weekly injections In interstitial keratitis the iodides are contraindicated and recourse should be had to intensive arsenotherapy combined with fever therapy in all but the mildest cases Fever therapy in this condition either in the form of malaria or the hypertherm combined with the administration of riboflavin is surprisingly efficacious Combined with tryparsa*mide therapy it is also of value in juvenile* paresis

Cure —Syphilis can as a rule be cured if treatment is begun early and is continued sufficiently long without interruption Un*fortunately there are no known conditions* the fulfilment of which will warrant the physician in giving final assurance of cure *but for his guidance the following criteria* have tentatively been adopted If during the twelve months immediately following the completion of a full course of treatment (see accompanying schedule) the patient receives no antisyphilitic medication develops no lesions and exhibits repeatedly negative Wassermann reactions and if at the end of that period a thorough examination including careful scrutiny of the cardiovascular and nervous systems and always the spinal fluid shows no progress of the disease then he may tentatively be regarded as cured But he must not be dismissed entirely He should be examined from time to time at gradually lengthening intervals for the rest of his life

YAWS

Definition —Yaws is a specific disease caused by a spirochetal organism *Treponema pertenue* It is largely limited to tropical countries and is characterized by an initial cutaneous lesion which is *followed* by a multiple papular granulomatous skin eruption and in some instances by late destructive lesions of the skin *and bones* Lesions of the soles of the feet are especially common Among synonyms for the disease are frambesia tropica pian *(French)* bouba (Spanish American) and parangi (Ceylon) Many others are listed by Hermans (1931)

History —The earliest reliable accounts of yaws now available date to the Seventeenth Century Since Negroes were brought from Africa to the West Indies as early as 1510 it cannot be determined whether yaws was introduced into the Americas *through* this means or whether the disease already existed among the native tribes Undoubtedly it was prevalent among slaves imported from Africa and by the Eighteenth Century yaws had become a *serious* problem on plantations in the West Indies

Etiology —The spirochete of yaws (*Treponema pertenue*) was *first* described by Castellani in 1905 soon after the discovery of *T pallidum* by Schaudinn The organism *measures from* 8 to 20 microns in length and about 0 2 micron in diameter It has six

to fourteen closely placed spirals and morphologically is indistinguishable from the spirochete of syphilis It is best seen in the fresh state by dark ground illumination The organism stains with difficulty

Among laboratory animals *Treponema pertenue* is pathogenic for monkeys and rabbits and gives rise to subclinical infection in mice rats and related species (Schobl 1928 Pearce and Brown 1925) At ordinary temperatures the organism survives for only a few hours when removed from a living host It cannot be grown on artificial media When stored at the temperature of solid carbon dioxide (—78° C) it remains virulent for several years (Turner 1938)

Epidemiology —*Distribution and Prevalence* —Yaws as an endemic disease is practically limited to the tropics It is particularly common in equatorial Africa the West Indies parts of India Ceylon, the Philippines the Dutch East Indies and throughout the entire group of Southern Pacific Islands Endemic foci occur in parts of Brazil and Colombia in South America and in several countries of Central America Only sporadic cases have been reported from North America and Europe The disease is not distributed uniformly however even within the tropics The situation in Jamaica as found by the epidemiologic studies of the Jamaica Yaws Commission (Turner Saunders Kumm and others 1935–1937) is interesting and may be representative of that in other countries In that country the distribution of yaws is very uneven Areas of high prevalence lie within a few miles of communities in which it is rarely encountered and there is a close correlation between its prevalence and certain environmental factors Where yaws is common there is practically always found a heavy rainfall and a fertile moisture holding soil supporting an abundant vegetation

It is principally a disease of rural peoples the lowest social and economic groups showing the highest attack rate The disease is most prevalent among Negroes and East Indians but cases are observed among mulattoes whites and Chinese In the South Pacific Islands it is Melanesians and Polynesians who are most affected There is no clear evidence of racial immunity

Yaws is usually acquired in childhood but no age is free from the risk of infection In one community in Jamaica (Bath) prevalence rates rose from 20 per cent among all children under five years of age, to 75 per cent among those ten to fourteen years of age In that area 33 per cent of the general population under twenty years of age showed active yaws lesions at the time of the study while among persons over that age 14 per cent showed active lesions Approximately 90 per cent of all persons found to have infectious lesions were under twenty years of age

Transmission —Yaws can be transmitted by direct person to person contact but it is probable that nonbiting insects also play a role in the spread of the disease There is no evidence for the existence of an animal or avian reservoir The initial yaws lesion which develops at the point of implantation of the spirochete is frequently observed at the site of a previous injury and is located on the lower extremity in the majority of cases Sexual transmission rarely occurs Transmission from mother to child *in utero* has not been established

Since earliest times the possibility of transmission by insects has been recognized Studies in Jamaica (Kumm and others 1935–1936) indicate that in this country a small gnat *Hippelates pallipes* is a likely mechanical vector This insect abounds where yaws is prevalent and in general is scarce where the incidence of yaws is low It feeds avidly on human sores and abrasions and has a predilection for lesions about the feet and legs When the fly feeds on an infectious yaws lesion material containing *Treponema pertenue* is taken into the esophageal pouch where the spirochetes may retain active motility for seven hours Upon feeding again which the fly may do repeatedly within the space of a few hours material from the esophageal pouch or diverticulum is regurgitated onto the new lesion Actively motile spirochetes can be demonstrated in this vomit drop The spirochete apparently undergoes no life cycle in the fly for all traces of it disappear after about forty eight hours Rabbits have been infected by having Hippelates flies feed first on infectious human lesions and then after an interval on wounds of the back or scrotum of normal rabbits

should not be too aggressive in the beginning When it is recognized early medication should begin with the administration of mercury with chalk 0 015 Gm to 0 03 Gm (¼ to ½ grain) three times daily for one or two weeks, or with injections of bismuth subsalicylate in doses of 0 001 Gm per kilogram given at weekly intervals until three doses have been given Then sulfarsphenamine beginning with 0 005 Gm per kilogram gradually increased to 0 01 Gm per kilogram should be given intramuscularly at weekly intervals for ten weeks Following this the child should be given forty to fifty intramuscular injections each of sulfarsphenamine and bismuth arranged in alternating courses each of ten weekly injections In interstitial keratitis the iodides are contraindicated and recourse should be had to intensive arsenotherapy combined with fever therapy in all but the mildest cases Fever therapy in this condition either in the form of malaria or the hypertherm combined with the administration of riboflavin is surprisingly efficacious Combined with tryparsamide therapy it is also of value in juvenile paresis

Cure —Syphilis can as a rule be cured if treatment is begun early and is continued sufficiently long without interruption Unfortunately there are no known conditions the fulfilment of which will warrant the physician in giving final assurance of cure but for his guidance the following criteria have tentatively been adopted *If during* the twelve months immediately following the completion of a full course of treatment (see accompanying schedule) the patient receives no antisyphilitic medication develops no lesions and exhibits repeatedly negative Wassermann reactions and if at the end of that period a thorough examination including careful scrutiny of the cardiovascular and nervous systems and always the spinal fluid shows no progress of the disease *then* he may tentatively be regarded as cured But he must not be dismissed entirely He should be examined from time to time at gradually lengthening intervals for the rest of his life

YAWS

Definition —Yaws is a specific disease caused by a spirochetal organism *Treponema pertenue* It is largely limited to tropical countries and is characterized by an initial cutaneous lesion which is followed by a multiple papular granulomatous skin eruption and in some instances by late destructive lesions of the skin and bones Lesions of the soles of the feet are especially common Among synonyms for the disease are frambesia tropica pian (French) bouba (Spanish American) and parangi (Ceylon) Many others are listed by Hermans (1931)

History —The earliest reliable accounts of yaws now available date to the Seventeenth Century Since Negroes were brought from Africa to the West Indies as early as 1510 it cannot be determined whether yaws was introduced into the Americas through this means or whether the disease already existed among the native tribes Undoubtedly it was prevalent among slaves imported from Africa and by the Eighteenth Century yaws had become a serious problem on plantations in the West Indies

Etiology —The spirochete of yaws (*Treponema pertenue*) was first described by Castellani in 1905 soon after the discovery of *T pallidum* by Schaudinn The organism measures from 8 to 20 microns in length and about 0 2 micron in diameter It has six

yields large numbers of motile *Treponema pertenue*

After several months retrogression of the generalized lesions may begin The smaller lesions heal and the large frambesiform lesions tend to become smaller and less numerous but it may be many months be fore they have entirely disappeared Even then relapses are not uncommon so that infectious types of lesions may be present off and on for several years after the onset of the disease Eventually a stage of latency is usually reached but this stage may likewise be interrupted at intervals by the occur rence of more bizarre types of lesions in which *Treponema pertenue* cannot be readily demonstrated

After several years have elapsed skin lesions similar to the syphilitic gumma may occur These so called 'late lesions are characterized by tissue destruction and ulceration often involving large areas of skin and subcutaneous tissue *Treponema pertenue* cannot be found but other types of spirochetes notably *Spirochaeta refringens* may be present Healing often leads to ex tensive scarring which if located in the region of a joint may lead to contractures

Lesions of the soles of the feet are very common and account for a good deal of the disability from the disease Two types which may occur alone or together are recognized One type consists of one or more eroded papules somewhat analogous to the fram besiform lesion of the skin Instead of pro truding above the plantar surface however the papule lies at the base of a small open ing in the sole and is exquisitely tender Serum from these lesions is usually rich in *Treponema pertenue* Like other infectious lesions plantar papules are observed most commonly in the first years of the disease

The other type of plantar lesions consists of widespread hypertrophy stripping or fissuring of the superficial layers of the sole giving rise to a curious mottled pattern very characteristic of yaws There is usually no ulceration and *Treponema pertenue* cannot ordinarily be demonstrated Plantar hyper keratosis may occur at almost any period during the course of yaws it has been ob served in patients soon after development of the generalized rash as well as twenty years or more after infection

Bones—In the Jamaica series bone lesions were observed in about 15 per cent of all patients showing active manifestations On the basis of x ray changes two types are recognized although not infrequently both types are present simultaneously In the one type periosteal proliferation, similar to that seen in syphilis is the most prominent feature In the other type areas of rarefac tion or destruction in the shafts of the long bones are observed These areas are round or oval and usually multiple with a sur rounding zone of increased density Clin ically the patient complains of pain in the affected region and there may be tender ness and swelling of the overlying soft parts (Maul 1918) The bones of the forearms legs and hands seem most often to be affected, involvement of the skull pelvis and spine is rare Both periostitis and osteitis may occur either in association with infec tious skin lesions or in later years after the generalized skin lesions have healed

Other Yaws Lesions—Among the less common but more spectacular lesions of yaws are gangosa goundou and juxta articular nodules In *gangosa* the cartilagin ous and bony structures of the nose are partially or completely destroyed by a late ulcerative process Cutaneous leishmaniasis may cause somewhat the same picture *Goundou* is an egg shaped paranasal en largement arising from the superior maxil lary bone The tumors may be sufficiently large to interfere with vision (Strong and Shattuck 1930) *Juxta-articular nodules* are firm freely movable painless subcutaneous fibroid tumors situated in proximity to a joint

Differential Diagnosis—A case of yaws with typical generalized lesions cannot easily be confused with any other disease Individ ual lesions may resemble those of secondary syphilis or cutaneous leishmaniasis but when the case as a whole is considered little dif ficulty should be experienced Demonstra tion of the treponeme in skin lesions serves to differentiate yaws from all conditions except those of the syphilis group Late ulcerative lesions of yaws are often indis tinguishable from the tertiary lesions of syphilis The late effects of yaws ulcerative lesions contractures partial amputation of digits may resemble the lesions of leprosy

Pathology —The most characteristic lesion of yaws is the cutaneous papule or frambesioma Histologically, the lesion shows marked epithelial hyperplasia, with elongation of the papillae There is exudation of leukocytes on or near the surface with many lymphocytes and plasma cells in the dermis With silver stains the spirochetes of yaws are constantly found in large numbers in the epidermis and more superficial dermis There is no evidence that the spirochete is phagocytosed by polymorphonuclear leukocytes or histiocytes The smaller

Fig 33 —Yaws in a child showing generalized frambesiform lesions

skin lesions such as scaly macules and folliculopapules show these changes to a less degree The late ulcerative lesions of yaws are very similar histologically to syphilitic gumma Although the gross and microscopic picture of the frambesioma of yaws is fairly characteristic histologic criteria for the differentiation of the cutaneous and subcutaneous lesions of yaws and syphilis are in general unreliable (Williams 1935 Ferris and Turner 1937) Lesions of the bones occur but no histologic studies have been reported The occurrence of visceral lesions in yaws is still debated, although evidence is accumulating that the aorta is sometimes involved (Choisser 1929, Chambers, 1936 Weller 1937) With possible rare exceptions the central nervous system is not affected

Symptomatology —*Skin* —Within two to eight weeks after infection the initial or primary lesion appears at the point of implantation of yaws spirochetes This lesion is a granuloma and may develop into a large cauliflower like growth from which *Treponema pertenue* can be recovered (Fig 33) There is accompanying enlargement of the regional lymph nodes The initial lesion usually persists for several months and heals with scar formation

During the first weeks of the disease *Treponema pertenue* gains access to the blood stream and symptoms attributable to generalization of the organism soon become manifest These consist of widely distributed skin lesions often enlargement of the superficial lymph nodes bone and joint pains and in some cases clinically recognizable lesions of these structures Mild constitutional symptoms such as low grade fever loss of appetite and slight loss of weight may occur but in many cases the general health of the individual is not materially affected About this time blood serologic tests similar to those employed in the diagnosis of syphilis (Wassermann Kahn Eagle Hinton) become positive, increase rapidly in titer and remain positive for many years unless rendered negative by specific therapy

The generalized rash may comprise at first only scaly macular lesions More commonly however from the beginning the rash is polymorphous comprising scaly macules folliculopapules papules and most prominent of all large granulomas—the yaw or frambesioma which is characteristic of this disease As the disease progresses the frambesiform lesions become more numerous and larger the patient with a fully developed generalized frambesiform rash presents an arresting picture one which can scarcely be confused with any other disease The individual lesion stands out from the skin level like a giant wart measuring 0 5 to 4 cm in diameter The surface of the lesion which may be covered by a crust is granular like the surface of a raspberry—hence the name frambesia Serum from the lesion

by mouth should not be used unless the more efficient drugs are unavailable Late skin lesions as a rule respond promptly to the usual drugs but the more chronic lesions of the skin and bones are often refractory and may require local surgical treatment

In the countries of high prevalence effectual control of yaws depends upon reducing the attack rate by bringing about a decrease in the source of infection *i.e.*, the infectious cases in the community through treatment The control measures instituted by the Jamaica Yaws Commission comprise the following First a survey of a given area for the purpose of detecting all infectious cases was made by sanitary inspectors then treatment of these cases with six weekly injections of either neoarsphenamine or bismuth and finally, close observation of the community so that new infections which arose could be treated promptly Since over 90 per cent of the infectious cases were among persons under twenty years of age it was to this part of the general population that control measures were directed By these measures it was possible to reduce the attack rate of yaws by at least 80 per cent (Turner Saunders and Johnston 1935 Saunders 1937)

GANGOSA

Gangosa is the term applied to a chronic ulcerative and destructive lesion involving the soft parts and cartilaginous portions of the nose The destructive process may extend to the bony structure of the nose the nasopharynx and the cutaneous tissue about the nose and mouth The lesion occurs most often as a late manifestation of yaws and consequently is now seen principally in the tropics It may likewise be caused by syphilis and while it is now rarely encountered in that disease there are many references in the older literature to a similar lesion Gangosa may rarely be caused by cutaneous leishmaniasis

In yaws the lesion usually begins as a gumma of the nasal septum or as a cutaneous lesion about the alae nasi Extension of the destructive process occurs over a period of months or years abetted perhaps by secondary invaders In advanced cases the entire nose is destroyed leaving a large opening directly into the nasopharynx There may be extensive ulceration of the surrounding soft parts and the floor of the nasal passages may communicate with the oral cavity because of partial destruction of the palate During the course of the active process there is commonly a foul smelling discharge Even without specific treatment some degree of healing eventually takes place Treatment for yaws will ordinarily arrest the destructive process Neoarsphenamine or mapharsen together with potassium iodide yield the best results but permanent disfigurement can rarely be prevented There is evidence which indicates that gangosa is becoming much less common in those tropical countries where yaws is being effectively treated

THOMAS B TURNER

RAT BITE FEVER

Definition —Rat bite fever is an acute infectious disease contracted usually from the bite of a rat and occasionally from the bites of other animals At present the etiology is in a confused state because as Brown and Nunemaker point out two apparently different micro-organisms *Spirillum minus* and *Streptobacillus moniliformis* have been considered individually responsible for the same clinical picture in man This confusion makes differentiation difficult if not impossible The spirillary infection (or so

Relationship to Other Spirochetal Diseases.—There are a number of diseases which belong to the same general group as yaws. Included among this group are syphilis, which is world wide in its distribution; bejel (Hudson, 1936) which is common among the Bedouin tribes of Syria and adjacent countries, and mal del pinto, common in parts of Central and South America, and recently discovered (Blanco 1938) to be caused by a spirochete similar to the organisms of yaws and syphilis. The precise relationship of these diseases to each other has not been determined but it is significant that for many generations practitioners have found sufficient clinical and epidemiologic differences between them to warrant the universal use of distinguishing names for each disease entity. These diseases have many features in common, but the vast majority of persons with each disease present a succession of signs and symptoms which, when taken as a whole, are very characteristic. This is particularly true with regard to yaws and syphilis; the other members of the group, bejel and pinto, have been less well studied as yet. Immunologically the situation is confused. Experimental and epidemiologic data indicate that there is some reciprocal immunity between syphilis and yaws but that this is by no means complete. Syphilis apparently gives rise to a greater degree of protection against yaws than yaws does against syphilis.

The main question therefore is whether the differences between yaws and syphilis are due to variations in the environment to which the host is subjected or whether they are due to inherent differences between the causative agents. The preponderance of evidence indicates that there are biologic differences between *Treponema pallidum* and *T. pertenue* and that these differences account in large measure for the distinctive clinical features of each disease. Perhaps in the remote past *T. pertenue* and *T. pallidum* were identical but there is no good evidence to indicate that differentiation occurred within historic times. Further discussion of this interesting question will be found in the writings of Blacklock (1937), Butler (1936), Stannus (1936) and Turner (1937).

Prognosis.—The disease is rarely directly fatal except in young infants. Without treatment the disease leads to months of partial incapacity, with the possibility of relapses over a period of many years. A not inconsiderable proportion of infected persons apparently go on, after many years, to spontaneous clinical and serologic cure. The indirect mortality from the disease due to secondary infection of cutaneous ulcers or bone lesions is probably higher than commonly supposed. With early treatment the prognosis is entirely favorable.

Prophylaxis.—No methods of artificial immunization are available. In regions where yaws is prevalent the chances of infection can be reduced by avoiding minor injuries to the skin and by protecting all open wounds and abrasions from contamination by flies. Children with infectious lesions should be excluded from school until rendered noninfectious by treatment. Efforts to control insect vectors are not practicable at the present time.

Treatment.—Yaws responds to the same drugs that are used in the treatment of syphilis, although satisfactory results and even cures are obtained in yaws with less treatment than is necessary in syphilis. The initial and generalized lesions of yaws heal promptly following the administration of the arsenical drugs. Treponemes usually disappear within two to seven days after the first injection. With four to six weekly injections a large proportion of patients remain clinically well and in many, blood serologic tests become negative. The weekly dose of neoarsphenamine is, for adults, 0.6 to 0.9 Gm. and for children 0.06 Gm. per 10 pounds of body weight. The weekly dose of mapharsen for adults is 0.04 to 0.06 Gm. and for children, 4.5 mg. per 10 pounds of body weight. These drugs should always be given intravenously. Infants and small children may be given sulfarsphenamine intramuscularly 0.1 Gm. per 10 pounds of body weight.

The lesions of yaws respond more slowly to bismuth and in general the results seem to be somewhat less satisfactory with this drug than with the arsenical preparations. Bismuth subsalicylate in oil 0.04 Gm. per 25 pounds of body weight intramuscularly is among the best of the bismuth preparations. Stovarsol (acetarsone) by mouth may be used but is not recommended. Mercury

names since the basic discoveries of Schottmuller and Blake The organism is extraordinarily pleomorphic and appears to have as one stage the so called L_1 forms of Kleineberger representing the phase of pleuropneumonia like organisms *Streptobacillus moniliformis* can be isolated from blood cultures and lesions The definitive bacteriological investigation requires highly specialized technics The sera of infected individuals contain agglutinins for the *Streptobacillus*

Pathology —There have been very few recorded autopsies of cases of rat bite fever The local lesion which is a granuloma without suppuration shows necrosis of the epithelium and dense round-cell infiltration of the corium Similar round cell infiltration occurs with the dilated vessels in the lesion of the skin eruption Lesions in the organs are chiefly those associated with a long continued febrile disease

Symptoms —In uncomplicated cases the wound of the rat bite heals promptly After an incubation period of five to fourteen days (average thirteen days with occasional long incubation periods of six weeks or more) the site of the wound swells becomes purplish and painful A chancre like indurated ulcer with a black crust may occur here and on the broader parts of the body may reach a diameter of 5 to 10 cm The regional lymphatics are inflamed and the adjacent lymph nodes become enlarged and tender The development of the local lesion is accompanied by malaise and headache and a sharp rise of temperature usually with a chill After this periods of fever alternate with afebrile periods The temperature rises abruptly to 103° to 104° F remains elevated for twenty four to forty eight hours and falls rapidly to normal within about thirty six hours The intervening afebrile periods last from three to nine days This relapsing type of fever may continue for weeks or months in untreated cases gradually subsiding Within the first week of the beginning of the fever the characteristic skin rash usually appears This is a purplish maculopapular eruption on the skin of the arms legs and trunk and occasionally on the face and scalp The skin lesions do not ulcerate They fade somewhat during the afebrile periods and reappear with new patches of eruption during the paroxysms of fever In addition to these cardinal symptoms of recurrent inflammation at the site of infection relapsing type of fever, and characteristic skin eruption there are numerous other symptoms Pains in the muscles and joints headache and vertigo are common Arthritis may occur Delirium coma and an urticarial rash with puffiness of the face occur in some cases The urine may contain albumin and casts The liver is not enlarged and there is no jaundice In long continued infection the patient becomes emaciated and secondarily anemic The erythrocyte count may be decreased to 1,400 000 and the hemoglobin to 25 per cent Leukocytosis with counts of 12 000 to 20 000 is usual at the beginning of the disease In old cases lymphocytosis has been observed A slight eosinophilia may occur during the eruptive stages During remissions most of the symptoms disappear or become less conspicuous

The Wassermann reaction is usually negative when syphilis can be excluded Positive Wassermann and Kahn reactions have been reported

The untreated disease tends to come to an end in a natural cure after several months But there are reports of infections prolonged over four eight and twenty years The mortality is said to be 10 per cent This is too high an estimate Many fatalities were due to secondary pyogenic infection Death should be rare in uncomplicated cases if properly treated

Diagnosis —The history of a rat bite followed after an incubation period of about two weeks by recurrent inflammation at the place of the bite lymphangitis and lymphadenitis relapsing fever and the characteristic skin rash is strongly suggestive of rat bite fever Sometimes there is no clear history of the bite and no local lesion when the patient is seen The rash may not be conspicuous The differential diagnosis to be considered would depend upon the area in which the patient lived As a rule it would be necessary to differentiate between undulant fever tularemia relapsing fever dengue trench fever malaria and erysipelas

The definite diagnosis should be based upon demonstration of the *Spirillum* by laboratory tests These are in order of value

doku) appears to be characterized more frequently *by an indurated ulcer at the site of* inoculation remittent fever and a purplish maculopapular rash The disease caused by the streptobacillus seems to be more often associated with abscess formation arthritis *and a variable type of fever* Neoarsphenamine and other arsenicals used in sufficient and repeated doses are effective in most of the cases of the spirillary type of infection These drugs appear to be less effective or ineffective in the streptobacillary disease Judgment must be withheld however until the etiological question is clarified This article is written by one who believes that while there are several types of *rat bite disease,* with different etiology the typical rat bite fever (sodoku) is caused by *Spirillum minus*

History—Interest in this ancient disease began with a report by Wilcox of the case seen by him in Louisiana in 1839 The modern period of study dates from Miyake's monograph on Rattenbisskrankheit *in 1900 The introduction of the Japanese name of the* disease sodoku (from *so* a rat, and *doku* poison) is also attributed to Miyake The causal agent of the *disease useful diagnostic laboratory tests and an* efficient method of treatment have been discovered by Japanese investigators

In 1914 Schottmuller isolated a Streptothrix from lesions of a case diagnosed as rat bite fever This was confirmed by Blake in 1916 The work of Dawson in 1939 indicates that the organism causing this type of rat bite infection is probably *Streptobacillus moniliformis* (*Haverhillia multiformis*) This has been confirmed by the extensive investigations of Brown and Nunemaker

Incidence and Geographic Distribution—Cases have been reported from nearly every part of the world It may be anticipated that cases of the disease will be discovered in every country where rats and man live in close association Bayne Jones collected seventy five case reports from the medical publications of the United States over the period from 1840 to 1930 Brown and Nunemaker completing the collection through 1940 have added forty four cases making a grand total of 125 reported from this country The disease is not common but its actual incidence cannot be estimated

Etiology—Francis has reemphasized the fact that rat bite fever is primarily a disease of wild rats transmissible to other rats to other animals and to man by the bite There is no evidence that fleas or other insects serve as vectors and there is no record of the transmission of the disease from man to man by excreta or fomites Cases attributable to the bites of cats ferrets and weasels have been reported

The incidence of the disease in rats is not known with certainty Reports indicate that from 2 to 21 per cent of rats in different colonies may be infected

The infecting organism is carried into the wound of the bite by the teeth or by material from the rat's mouth or lips falling on the surface of the wound The *Spirillum* has not been found in the saliva of rats It may get into the mouth and on the teeth from blood from injured gums lesions in the mouth, infectious conjunctival exudate draining through the lacrimal ducts or exudate from pulmonary lesions The *Streptobacillus* is found frequently in the exudate of chronic sinusitis chronic middle ear disease and chronic pulmonary infection in rats When several persons have been bitten by an infected rat often only the first victim has contracted the disease

Rat bite fever begins as a wound infection As this wound may be infected with organisms other than *Spirillum minus* other forms of rat bite disease occur A variety of cocci, bacilli and streptothrices have been found in these conditions Severe and fatal infections usually of a pyogenic and septicemic nature have been due to these accompanying or secondary micro organisms

The spirillary cause of rat bite fever was discovered by Futaki and his associates *in* 1916 They called the organism *Spirochaeta morsus muris* It is a spiral 3 to 5 microns long approximately 0 2 micron thick with pointed ends carrying one or more flagella The body is twisted in 1 to 4 angular spirals with crests about 1 micron apart It has never been cultivated in artificial media Robertson has identified it with *Spirillum minus* which Carter discovered in the blood of a rat in 1887 Other authorities have classified *it as a treponema or a new variety* of spirochete This organism has been found in nearly all cases in which a proper search for it has been made by inoculation of mice or guinea pigs The disease has been produced in man by inoculation of material containing the *Spirillum*

The organism now called *Streptobacillus moniliformis* has appeared under a variety of

during an epidemic in Berlin This observation was confirmed by Munch who in 1874 inoculated himself with blood containing motile relapsing fever spirochetes and subsequently developed the disease also by Motschutkoffsky (16 6) who proved the infectivity of the spirochete by inoculating the blood of patients into healthy persons

In 1891 Flugge suggested that the human body louse might act as a vector and Mackie (1907) in India reached a similar conclusion This belief was later confirmed by the inoculation into monkeys of crushed lice taken from relapsing fever patients In 1904 Ross and Milne in Uganda, showed that the "tick fever" mentioned by Livingston in 1857 was caused by a spirochete which invaded the peripheral blood stream These observations were confirmed in the Congo by Dutton and Todd (1905) who reported the mechanism of infection in the tick *Ornithodorus moubata* and the hereditary transmission of the spirochetes through the egg to succeeding generations of ticks

French Sudan and (4) on many occasions during the past the disease has been imported from Europe to the United States and has caused epidemics in cities along the Atlantic Coast In 1869–71 there was a widespread American epidemic which affected New York City Philadelphia Washington D C and many other cities

The *tick borne* relapsing fevers are endemic in (1) Africa especially tropical Africa and North Africa (2) Asia including Arabia Persia India and other parts of Central Asia (3) Europe including Spain (4) North America including Canada the United States and Mexico (5) Central

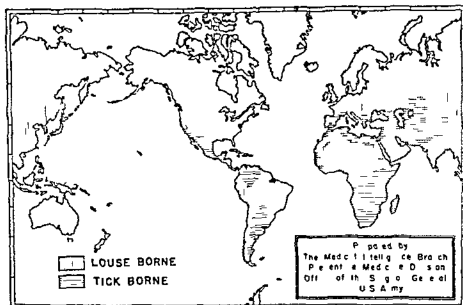

Fig 34—Geographical distribution of relapsing fever

Geographical Distribution—Relapsing fevers occur in many parts of the world as is indicated graphically in the accompanying map (Fig 34) and the distribution is influenced by various factors including the distribution of the arthropod vectors

The *louse borne* relapsing fevers have been reported as endemic in the following regions (1) Europe including the British Isles Denmark Germany Poland Russia the Balkans and Turkey (2) Asia including India China Japan Manchuria Persia and Siberia (3) Africa especially in Northern Africa including Egypt Algeria Abyssinia and Sudan and in Western Africa including the Gold Coast Nigeria Senegal and the

America and (6) South America including Colombia Venezuela Peru Uruguay and the Argentine Republic In the United States the disease has been reported in California Colorado Arizona Texas and Kansas Because of the manner of their transmission the tick borne fevers rarely become epidemic

Etiology—*The Spirochetes*—The relapsing fevers are caused by spirochetes similar to the *Spirochaeta recurrentis* discovered by Obermeier in 1868 which are demonstrable in the blood of patients *during the* febrile periods According to Bergey's Manual on Determinative Bacteriology 1940 the genus *Borrelia* Swellengrebel in

1 Inoculation of white mice and guinea-pigs with the patient s blood, exudate from the initial lesion, serum expressed from exanthematous patches material aspirated from lymph nodes or ground up pieces of tissue excised from lesions These animals are susceptible, develop infection from inoculation with very few organisms and pass through characteristic stages of the disease, with the spirilla in their blood White mice often harbor this infection spontaneously causing errors in diagnosis It is essential to ascertain by examination of the blood that these animals are free from spirilla before inoculations are made Inoculations of mice should be controlled by injections of the same suspected material into guinea pigs

2 Examination of blood and exudate from lesions by dark field illumination and stains Reports of the finding of the *Spirillum* in the blood of man are questionable It may be found in material from the lesions Wright's and Giemsa's stains are satisfactory The flagella can be demonstrated best by the use of the Tribondeau Fontana silver stain

As the organism has not been cultivated blood cultures at present offer no assistance Mistakes in examination of these cultures have been made by failure to distinguish between 'artifact spirochetes and actual organisms

Treatment —The local lesion should not be incised In 1912 Hata cured patients with rat bite fever by giving them injections of salvarsan Since then salvarsan and its derivatives have been shown to be specifically effective remedies One or two injections of the usual doses (0 1 to 0 6 Gm) of salvarsan arsphenamine neoarsphenamine, and similar compounds have brought about cure promptly Occasionally ten or more injections may be needed Other arsenical compounds bismuth and mercury have not been effective in therapy

Paresis Therapy —In 1926 Solomon and his associates recommended experimentally induced rat bite fever as a substitute for malaria in the treatment of general paralysis The infection in man has been established by the injection into the skin of the patient of 0 1 cc or less of blood from an infected guinea pig The disease thus produced is apt to be severe and may have undesirable features This form of treatment of paresis is not recommended

RELAPSING FEVER

(*Febris Recurrens Spirillum Fever Famine Fever Mianeh Fever Carapata Disease Tick Fever Kimputu*)

Definition —The term relapsing fever is applied to a large group of acute infectious diseases, clinically similar but etiologically distinct which are prevalent in many parts of the world These diseases are characterized by an initial febrile period lasting from three to ten days which usually begins and ends abruptly and is followed after several days of apparent recovery by one or more relapses If untreated the total course of the infection may last from six to eight weeks The relapsing fevers are caused by various closely related species of spirochetes of the genus *Borrelia* which are demonstrable in the patient s blood during the febrile attacks The infections may be divided into two large groups namely the louse borne and the tick borne relapsing fevers

History —The first known description of relapsing fever was afforded by Rutty who in 1739 reported an epidemic at Dublin The name "relapsing fever was proposed by Henderson who in 1843 described an epidemic in Edinburgh and who differentiated the disease from typhus fever In 1868 Obermeier (1873) discovered the causative spirochete in the blood of relapsing fever patients whom he studied

Palestine *O marocanus* in Spain and Morocco *O venezuelensis* and *O talaje* in Northern South America Central America and Mexico *O turicata* in Texas and Kansas and *O hermsi* in California

Available experimental data indicate that within a few days after the tick ingests infected human blood the spirochetes disappear from the digestive tract but within several days they multiply in the Malpighian tubules and other organs including the coxal glands salivary glands and legs It appears probable that the tick does not transmit the organisms through its proboscis while biting but that infection occurs by contamination of the skin puncture wound with the spirochete containing fecal fluid excreted by the tick The spirochetes are transmitted from adult female ticks through the eggs to their offspring for at least three generations Ticks of the species *O turicata* have remained infected for at least six and one half years There appears to be no specific relationship between the kind of tick and the species of spirochete

It is now believed that ticks normally become infected by feeding on infected lower animals Such animal reservoirs are probably afforded in West Africa by a shrew mouse in Panama by a wild monkey *Leontocebus geoffroyi* in Texas by armadillos and opossums and in California by squirrels and chipmunks and probably other animals

Pathology —The spirochetes may be found in the blood and the internal organs especially the spleen and the brain but the autopsy findings are not diagnostic Often the skin is jaundiced and there may be numerous small subcutaneous or submucous hemorrhages The spleen is enlarged and histologically it shows simple hyperplasia The liver is slightly enlarged Hemorrhagic meningitis has been reported It appears likely that death is rarely caused by the relapsing fever but can be attributed to complicating conditions and infections

Symptomatology —The many types of relapsing fevers described in various parts of the world naturally differ considerably in their clinical characteristics Wide variations also occur in the symptoms observed in a single epidemic Manson Bahr has described five clinical types as follows (1) A cosmopolitan type due to *S recurrentis* (2) an Iranian type due to *S persica* (3) a Central African type caused by *S Duttoni* (4) a Spanish type due to *S hispanicum* and (5) a Central and South American type produced by *S venezuelensis* Strong has discussed the symptomatology of the relapsing fevers of Africa North Africa Europe India China Persia Panama and North America

The more important characteristics of these different types may be briefly summarized as follows

The incubation period is estimated at from two to fifteen days the average being about seven days

The initial attack may last from two to seven or more days It usually starts abruptly with chilliness or a chill followed by a high fever intense headache pains in the muscles and joints nausea vomiting photophobia dizziness and sometimes epistaxis The temperature rises quickly to 104° or 105° F or higher and except for slight morning remissions it remains elevated throughout the initial febrile period at the end of which it falls to normal by crisis The pulse also rises quickly and soon reaches 110 to 140 beats per minute Periods of sweating may occur during the first day but thereafter the skin is hot and dry and the face is flushed Jaundice may occur but is more likely to appear later An erythematous rash is common during this period and later rose colored spots may occur on the trunk and limbs According to Manson Bahr the rash generally is most marked in the region around the neck spreading in a semicircular fashion from the tips of the mastoid processes thence it ranges in a symmetrical manner round the shoulders down the sides of the chest and abdomen to the inner aspects of the thighs and to the extensor and flexor aspects of the forearms The individual petechiae may be as large as a three penny bit and need to be carefully differentiated from the exanthemata of typhus and hemorrhagic smallpox Labial herpes may occur

Frequently the patient complains of severe headaches and of muscular and joint pains In case of high fever there may be delirium Insomnia may be an important symptom and hyperesthesias of the taste and tactile senses may occur It has been suggested that the spirochetes of relapsing fever

cludes six species which cause relapsing fevers in the following regions *B recurrentis* (European), *B duttonii* (West African) *B kochii* (East African) *B berbera* (North African) *B carteri* (Indian) and *B novyi* (American)

BACTERIOLOGY —Morphologically these spirochetes are indistinguishable and in general they conform to the description of *Borrelia recurrentis* This is a delicate spiral thread like organism 8 to 30 microns long and 0 3 to 0.5 micron thick, with pointed ends and from 4 to 10 large wavy irregular coils There is a spring like axial filament on which there is a layer of contractile protoplasm enveloped in a delicate periplast also fine terminal filaments but no flagellae The organism can move in either direction The spirochetes may be stained with the ordinary aniline dyes and preferably by methods commonly used for staining blood films They can be destroyed by exposure to 10 per cent saponin or to 10 per cent bile salts

Methods are available for cultivation of the organisms in artificial media Noguchi used ascitic fluid containing a piece of sterile rabbit kidney and a few drops of citrated blood, incubated at 37° C under anaerobic conditions Later workers have used semi solid media or developing chick embryo As such culture methods sometimes fail they are rarely used for routine diagnosis

Certain lower animals are susceptible to experimental infection and according to Novy and Knapp *B recurrentis* *B novyi* and *B duttonii* have been differentiated according to their infectivity for monkeys mice and rats It is claimed that rabbits and guinea pigs are relatively unsusceptible although they may be infected with *B carteri* and guinea pigs have been infected with some American strains It is of interest to note that spirochetes resembling those of relapsing fever but producing different symptoms have been found in various natural infections of lower animals and birds

In man and in animals recovery from the infection is followed by a transient immunity and the appearance in the serum of specific spirocheticidal lytic and agglutinating antibodies

Transmission —Relapsing fever can be transferred by the injection of blood containing the spirochetes into normal persons The organisms are able to penetrate the mucous membranes of the eye and possibly of other parts of the body they can also cause infection when rubbed into the apparently intact skin It appears that under natural conditions the disease is spread by blood sucking arthropods which may act either as contaminated mechanical carriers of infection or as biological vectors Fleas bedbugs lice and ticks have all been suspected as potential carriers but most of the infections appear to be spread either by lice or by ticks

LICE —Human lice (*Pediculus humanus* var *corporis* and var *capitis*) have long been accepted as vectors of *B recurrentis* (Syn *S recurrentis*), the cause of European typhus fever Manson Bahr believes that *S novyi* *S carteri* and *S berbera* are similar to *S recurrentis* and that the fevers which they cause in Europe Asia and North America are conveyed by lice Stron states that European Indian Chinese West African and some of the North African infections are transmitted by the louse *P humanus*

Lice feeding on patients during febrile periods may ingest spirochetes some of which survive the louse s gastric juice quickly enter the hemocele and are distributed throughout the entire body cavity After four to six days the organisms become abundant in the hemocele and the louse contains infective spirochetes for several weeks and possibly during the rest of its life The organisms do not pass through the egg to the louse s offspring Apparently the infection is transmitted to man not by the bite of the louse or through contamination with the feces but by crushing the infected louse on the human skin The released spirochetes may then enter the skin or contaminate the fingers and thus reach the mucous membranes of the eye

TICKS —The tick borne relapsing fevers caused by *B duttonii* and other species or varieties of spirochetes are transmitted by ticks of the family *Argasidae* especially of the genus *Ornithodorus* The following species have been suspected or shown to be vectors *O moubata* in Southeast and Central Africa *O erraticus* in Tunis *O papillipes* and *O tholozani* in Central Africa and

they may be present in the afebrile period If spirochetes are not demonstrable microscopically, specimens of blood should be injected into white rats or white mice The blood of these animals should then be examined for spirochetes daily for several days

Prognosis —The reported mortality has usually been low 2 to 6 per cent but in certain epidemics in West Africa the death rates have exceeded 50 per cent The deaths usually occur among weak poorly nourished individuals especially young children and the aged Untreated cases may last as long as six to eight weeks However the disease can be cured in a short time by treatment with neoarsphenamine or related arsenicals

Immunity —Recovery from an attack of relapsing fever confers a transient immunity at least to the same type of spirochete It also produces specific antibodies in the serum Possibly the relapses are usually less severe than the initial attack because the immunity increases with each relapse until the infection is overcome It has been reported that reinfection can occur in man as early as two months However the natives of endemic regions appear to possess considerable immunity which probably is acquired through repeated infections

Prevention —The prevention of relapsing fever naturally depends on the protection of susceptible individuals from the arthropod vectors The louse borne fevers can be prevented by taking all of the precautions necessary to avoid exposure to body or head lice These measures include the maintenance of good personal hygiene and cleanliness and the disinfestation of lousy persons and clothing

The tick borne infections are more difficult to control as these arthropods do not live on the victim but as a rule live in the floor or walls of native houses in the earth of old camp sites in cracks in the floors and walls of caves and in the burrows of various small animals Such places should not be selected as camp sites and care should be taken to avoid exposure to ticks which usually come out of their hiding places at night and feed on their hosts

According to Manson Bahr a prophylactic vaccine made of killed cultures of *S recurrentis* has been used by Russian workers and found to produce specific spirochetolysins in the serum However, attempts to protect animals with killed vaccines have failed

Treatment —The patient should be kept in bed given a liquid diet and treated both symptomatically and specifically The specific treatment usually recommended consists of a single intravenous injection of neoarsphenamine or some related arsenical compound According to Manson Bahr (1940) who prefers novarsenobillon the arsenical should be given when the temperature is on the rise and not when it is declining or during the apyrexial period If treatment is not begun during the initial attack one should wait until the first relapse and then give it as the temperature rises If given at the time of the crisis, a severe reaction may occur due to the liberation of large amounts of toxic materials from the bodies of the destroyed organisms and in certain types of infection such as the Central African relapsing fever this may on rare occasions cause a fatal collapse Albuminuria is not considered a contraindication to the use of arsenicals

Neoarsphenamine is commonly recommended for use intravenously in doses of 0 01 Gm for each kilogram of body weight A single dose usually cures but two or three doses may be required Mapharsen has been used in a few cases with good results and it is believed that this drug may eventually replace neoarsphenamine It should be used in doses of from 0 04 to 0 06 Gm intravenously

Certain observers have reported cases in which neoarsphenamine failed to cure the disease and in these various other drug have been tried including bismuth preparations gold salts and the serum of convalescent individuals The therapeutic value of these materials has not been determined When intravenous injections cannot be given stovarsol may be used by mouth in doses of six tablets (4 gr or 0 25 Gm each) daily

are neurotropic They may persist in the brains of the experimental animals for periods of more than a year In the tick borne Central African type, *severe nervous lesions* have been noted On rare occasions, optic atrophy has occurred immediately after the fever or several months later At times hemiplegia aphasia or other nervous symptoms may occur suddenly during the disease *In such instances the spirochetes may be* demonstrable in the cerebrospinal fluid which also contains an excess of lymphocytes and is under increased pressure Cases have also been reported with symptoms resembling encephalitis and meningitis

The tongue is usually coated and moist but in severe cases it may be dry and brown Nausea and vomiting are common and they may persist even during the apyrexial period The vomitus may contain bile or it may resemble the black vomit of yellow fever Anorexia is common and the patient usually is constipated however diarrhea has been associated with severe types of the disease Abdominal pain is a common symptom and gastric or intestinal hemorrhages have been reported The liver may be enlarged and tender, and jaundice may be severe The spleen is usually large and tender

Pulmonary symptoms including a bronchial catarrh frequently occur during the initial febrile period In some epidemics pneumonia occurs in 5 per cent of the patients and is a serious complication

Urine collected during the paroxysm may contain albumin less frequently casts and rarely blood Spirochetes have been found at times in the urine and prostatic fluid

Blood collected during the febrile attack usually contains spirochetes There is a polymorphonuclear leukocytosis of 15 000 to 26 000 and the Arneth count *is deflected to* the left In about 20 per cent of cases the Wassermann test is positive during the period of infection

The period of the initial attack usually ends abruptly with profuse sweating and a rapid fall of the temperature to normal or below This may be accompanied by diarrhea In elderly or weak patients a dangerous state of collapse may occur

The first period of apyrexia which follows the crisis of the initial attack lasts from three to ten days The fever and all of the other symptoms subside The spirochetes disappear from the peripheral blood stream *The skin becomes cool and* pale the pulse falls to the normal rate and is of poor quality The prostration is great at first but in a few days, the appetite and strength return and the patient feels so well that he considers himself completely recovered

The first relapse follows this symptomless interval It is characterized by a repetition of the more important symptoms of the initial attack It may be more severe, but as a rule it is milder Jaundice is more common Conjunctivitis may occur and iritis is not rare Transient cranial nerve defects may occur and there may be uterine hemorrhages or abortion The relapse seldom lasts as long as the first attack and it also ends by crisis

Subsequent Relapses—The end of the first relapse is often coincident with convalescence but in many instances additional relapses occur Frequently, these are shorter and milder than the previous febrile periods In the louse-borne relapsing fever of Europe and Asia there are rarely more than two three or four relapses This is also true of the tick borne infections of North America The tick borne infections of Persia and Central Africa usually have four or five relapses, and the latter may have as many as eleven relapses

Convalescence may be protracted and there may be various sequelae including iritis otitis parotitis adenitis neuritis, polyarthritis nephritis and pneumonitis

Diagnosis—The relapsing fevers may be confused with various other diseases including malaria dengue yellow fever Weil s disease enteric fever typhus influenza pneumonia and early smallpox They *may be differentiated from these diseases* on the basis of clinical differences However the specific diagnosis depends on the demonstration of typical relapsing fever spirochetes in the patient s blood This is commonly done by the microscopic examination of blood as follows (1) fresh preparations examined by dark field illumination (2) thin films prepared with Wright s stain (3) thick films stained with Wright s or Giemsa s stains The spirochetes are usually found during the febrile attacks but occasionally

necrosis with distortion of the normal lobular architecture Evidence of biliary stasis in the central part of the lobule has been described and signs of regeneration of liver cells may be prominent Capillary damage is indicated by the minute hemorrhages which have been described in nearly every part of the body They are most commonly found beneath the skin peritoneum and pleura and in the intestinal tract kidneys nasopharynx, and adrenal glands The hemorrhages are usually small but may occasionally be massive The skeletal muscles show signs of active inflammation and degeneration of the individual muscle fibers The gastrocnemius muscle is most commonly involved

Spirochetes are readily demonstrable (Levaditi s stain) in the kidneys and liver and have occasionally been found in other organs The pathologic lesions described in the kidney liver capillaries and skeletal mu cles are thought to be due to a direct toxic effect of the spirochete Such clinical features of Weil s disease as jaundice azotemia myalgia and the hemorrhagic diathesis are adequately accounted for by these pathologic lesions The exact mechanism of the jaundice is not clear Hepatitis appears to be responsible for the bilirubinemia but hemolysis and biliary obstruction may be contributing factors

Other less common pathologic findings include hemorrhagic pneumonia vegetative endocarditis myocarditis and inflammatory lesions of the intestinal tract The spleen and lymph nodes are usually not enlarged

Clinical Features —The average incubation period in Weil s disease is said to be ten days but may range from four to nineteen days The clinical course of the illness may be divided into the following stages

Septicemic Stage —The first stage of Weil s disease commonly associated with spirochetemia lasts from two to five days It is characterized by sudden onset with headache chilliness myalgia and prostration There may be anorexia nausea vomiting abdominal rigidity and cough with bloody sputum On physical examination the patient appears acutely ill There is high fever (102°–106° F) and frequently a relative bradycardia The skin is hot and dry petechial hemorrhages are not uncommon and the conjunctivae are injected The throat may be moderately inflamed and signs of bronchopneumonia are sometimes described The abdomen is usually soft although there may be tenderness of the abdominal wall The muscles of the legs and back are tender and signs of meningeal irritation are common These symptoms and signs increase in severity as the disease progresses

Icteric or Toxic Stage —It is estimated that not more than 50 per cent of patients with Weil s disease become jaundiced The nonicteric form of the disease passes from the first stage directly into the third or convalescent stage In the more severe cases jaundice develops (most frequently on the fifth day) and may become very intense Pruritus is rare At about the same time there appears evidence of renal failure with oliguria and even anuria The hemorrhagic tendency also becomes apparent in the second stage of the disease and is characterized by purpuric and ecchymotic spots in the skin and petechial hemorrhages in the mucous membranes and conjunctivae The patient appears profoundly ill and may lapse into coma or become disoriented and delirious

The temperature is lower than in the first stage (98°–101° F) but the pulse increases (100–130) and respirations may be rapid Signs of patchy consolidation are occasionally encountered in the lungs and the liver is enlarged and moderately tender The spleen is seldom palpable Moderate abdominal distention is common and tendon reflexes are diminished

In fatal cases death usually occurs between the ninth and sixteenth days In the nonfatal cases the patient s condition begins to improve late in the second week the sensorium gradually clears the urinary output increases and the jaundice subsides Occasionally iridocyclitis or optic neuritis may develop as a late complication

During the second stage of the disease the blood becomes sterile but spirochetes appear in the urine Specific antibodies are demonstrable in the blood serum between the ninth and fourteenth days

Convalescent Stage —Convalescence begins most frequently at the end of the second week of the disease The jaundice and

WEIL S DISEASE

(Spirochetal Jaundice Leptospirosis Icterohaemorrhagica Infectious Jaundice)

Definition —Weil s disease is a spirochetal infection caused by *Leptospira icterohaemorrhagiae* The disease is characterized by sudden onset with malaise prostration myalgia and fever and in many cases by the subsequent development of jaundice a hemorrhagic tendency and renal failure

History —As early as 1800 cases of jaundice complicated by hemorrhage conjunctivitis and renal failure were noted among French soldiers in Egypt An infection of apparently similar nature was described during the American Civil War In 1886 Weil published his classical description of jaundice occurring in young adults—a disease of sudden onset with severe shaking chills prostration hepatomegaly splenomegaly hemorrhagic diathesis and evidence of renal damage It is of interest to note that two of the features of the syndrome described by Weil (chills and splenomegaly) are now considered to be rarely associated with the disease which bears his name In 1916 Inada reported that Weil s disease was caused by a spirochete and two years later Noguchi classified the organism and named it *Leptospira icterohaemorrhagiae*

Incidence —Cases of Weil s disease have been encountered in at least forty six different countries The number reported from England France and Germany is well over 1000 and the infection has been common in Holland Denmark Japan Africa and South America The first case recognized in the United States was reported in 1922 and by 1941 sixty seven cases had been described in the American literature

The disease is far more common in men than in women the difference is apparently due to occupation The infection is relatively *uncommon in children and occurs most frequently* in adolescents and young adults The majority of cases occur during the summer months

Mode of Infection —*L icterohaemorrhagiae* has been demonstrated in the excreta of more than 10 per cent of adult gray rats trapped in rural and urban districts of this country It has also been recovered from dogs mice cats pigs foxes and horses The organism will survive for at least three weeks in stagnant water The commonest source of human infection is stagnant water which has been contaminated by murine excreta *The portal of entry is usually* an abrasion on the skin but may be the gastro intestinal tract the nasal mucous membrane or the conjunctiva Fish cleaners miners sewer workers tunnel diggers sugar cane cutters and workers in rice fields are the most frequent victims of the disease Each of these occupations involves work in wet places where rats are common Seventy-one cases were reported in Rotterdam among persons who had accidentally fallen into dirty canals or who had been swimming in a single infected swimming pool The infection may also be transmitted through contaminated drinking water

Pathology and Pathogenesis —Patients dying of Weil s disease are found to have prominent pathologic lesions in the kidneys liver capillaries and skeletal muscles The enlarged bile stained kidneys show swelling and necrosis of the epithelium of the convoluted tubules and interstitial infiltration of the kidney parenchyma with both lymphocytes and polymorphonuclear leukocytes Although glomerular lesions resembling those of hemorrhagic nephritis may occur the demonstrable renal damage is predominantly tubular The liver is often slightly enlarged No signs of obstruction are to be made out in the larger bile ducts and although inflammation and occlusion of the finer intrahepatic biliary ducts have been described they are thought to be uncommon Direct injury to liver cells is indicated by cloudy swelling and scattered areas of focal

failure or extensive hemorrhages The non icteric form of Weil's disease is rarely, if ever fatal

Treatment—Supportive treatment should consist of adequate salts and the administration of 3 to 5 liters of fluid a day during the febrile stage of the illness (by intravenous route if necessary) A liquid or soft diet should be prescribed high in carbohydrate and supplemented by intravenous glucose therapy if the jaundice is severe Daily enemata should be employed if necessary to combat abdominal distention Since the patient's excreta may be infected they should be sterilized before being disposed of

Arsenical drugs are relatively ineffective in the treatment of Weil's disease and their use is considered hazardous in the presence of liver and renal disease Soluble bismuth preparations (sodium bismuth tartrate) are effective in experimental leptospiral infections in guinea pigs and both soluble and colloidal bismuth compounds have been used with some success in human cases of spirochetal jaundice The most promising form of specific treatment however appears at present to be serum therapy Specific antiserum prepared in horses has been found to be effective in lessening the severity of the disease and decreasing the mortality particularly when administered early in the course of the infection Although rather extensively used in Europe specific antiserum is unfortunately not available at present for general use in this country Convalescent serum may serve as a satisfactory substitute in certain cases

Prophylaxis—Prophylactic vaccines containing killed cultures of leptospira have been employed particularly in Japan but the efficacy of vaccination as a preventive measure remains to be established Public health regulations designed to prevent workers from coming in contact with infected stagnant water are doubtless effective in lessening the prevalence of the disease

PROTOZOAN INFECTIONS

AMEBIC DYSENTERY

(Amebiasis Entamebiasis Amebic Colitis)

Definition—Amebic dysentery is a specific infection originating in the large intestine and characterized by discharges of blood and mucus Secondary lesions may occur, especially in the liver The causative microorganism is *Entamoeba histolytica*

There are many conditions in which diarrhea or dysentery may appear as an occasional symptom but in two infections namely bacillary and amebic dysentery the cardinal manifestation is a frequent discharge of blood and mucus The bacillary type of infection is a fairly simple process but amebic dysentery has commanded the attention of workers in several fields because of its interesting etiology its striking pathology and the comparatively satisfactory methods for its diagnosis and treatment

History—Attention was first directed to amebae as the possible cause of dysentery by Lösch in 1875 but his suggestion was not received very seriously on account of the occurrence of acute cases of dysentery without any amebic infection Amebic dysentery was established as a definite entity in 1891 by the pathologic studies of Councilman and Lafleur The situation was greatly simplified about 1900 when the etiology of bacillary dysentery was fully established but there was still much confusion because of the fact that amebae were frequently found in the stools of healthy people A definite step toward the clarification of this difficulty was taken by Schaudinn in 1903 He suggested that the amebae commonly seen in the feces of man could be separated into two distinct species—a pathogenic and a nonpathogenic type The former he named *Entamoeba histolytica* on account of its ability to dissolve tissues—the harmless form he called *Entamoeba coli* The recognition of a nonpathogenic ameba in the intestinal tract of man was a fundamental step in establishing the etiologic role of *E histolytica*

Nomenclature—Protozoologists readily distinguish the genus *Entamoeba* of man from a quite distinct type *Endomoeba blattae* living in a very differ-

evidence of renal insufficiency gradually disappear and the patient becomes symptom free except for weakness Convalescence may occasionally be prolonged for eight to ten weeks because of persistent jaundice Relapses are not uncommon in the third fourth or fifth weeks but they are usually mild lasting only a few days The specific antibodies reach a high titer in the blood *in the convalescent state and persist for* many years

Laboratory Findings—The urine particularly in the second stage of the disease, contains albumin casts and bile The stools are rarely acholic Leukocytosis (10 000–50 000) is present from the onset and is accompanied by an increase in the percentage of young polymorphonuclear leukocytes Anemia may occasionally develop but the platelets and prothrombin time are normal The icterus index may exceed 300 and the van den Bergh reaction is variable The nonprotein nitrogen and blood urea nitrogen of the blood are increased in the second week of the disease and the carbon dioxide combining power of the blood is depressed in cases of severe renal insufficiency In most cases examination of the spinal fluid gives evidence of meningitis in the early stages of the disease There is a moderate increase in spinal fluid protein the Pandy reaction is positive and the cell count ranges between 50 and 1000 cells per cubic millimeter Approximately half of the cells may be polymorphonuclear leukocytes

Specific Diagnostic Methods—*L ictero haemorrhagiae* may be recovered from the blood during the first week The organism is demonstrated with only the greatest difficulty by direct examination of the blood under the dark field microscope since filaments from red blood cells often float free in the plasma and are easily mistaken for leptospira The most practical method of bacteriologic diagnosis is the inoculation of blood intraperitoneally into a young guinea pig (175 Gm or less) Within ten to fourteen days the pig will usually become jaundiced and die and the organism can be identified at autopsy The organism may occasionally be recovered before the onset of jaundice by aspirating the peritoneal cavity

The spirochete of Weil s disease appears in the urine in the second week of the disease Dark field examination of the urine is unsatisfactory but guinea pig inoculation with the sediment of freshly voided neutral urine will often result in recovery of the organism The leptospira may occasionally be demonstrated in the spinal fluid or in the sputum by the same method

Specific antibodies which appear in the blood after the tenth to the fourteenth day are measured by the agglutination test The presence of agglutinins for *L icterohaemorrhagiae* in dilution of 1 300 or above is considered diagnostic Serum containing the specific antibodies also causes lysis of the organisms A negative agglutination reaction after the thirtieth day of illness practically rules out the diagnosis of Weil s disease Several immunologically different strains of *L icterohaemorrhagiae* however, have been described and Weil s disease may rarely be caused by a canine strain of leptospira (*Leptospira canicola*)

Differential Diagnosis—Early in its course Weil s disease simulates numerous severe infections associated with bacteremia the illness being frequently confused with *typhoid fever* Mild attacks of the nonicteric form of the disease resemble influenza

In the presence of icterus leptospirosis may be mistaken for acute *catarrhal jaundice* Elevation of the leukocyte count, the absence of lymphadenopathy and splenomegaly evidence of renal disease a hemorrhagic tendency and meningeal signs all serve to distinguish the spirochetal infection

Perhaps the most difficult problem in differential diagnosis is presented by *yellow fever* Certain features however, seem to distinguish it from Weil s disease Early in the course of yellow fever the patient s face is intensely flushed there is an appearance of anxiety and the pulse is rapid As the jaundice develops the pulse becomes slower whereas the reverse is true in Weil s disease The absence of leukocytosis and a normal red blood cell count are also distinguishing features of yellow fever

Prognosis—Reported case fatality rates for Weil s disease have varied in different epidemics from 4 per cent to 48 per cent. In a series of 452 cases studied in Holland 10 2 per cent of the patients died The prognosis is poor in individuals over sixty years of age and in those with severe renal

in the small intestine a four nucleated ameba emerging from each cyst Following nuclear division such forms give rise to 8 typical trophozoites which are commonly arrested at points of stasis in the large bowel such as the cecum and ascending colon and in the sigmoid flexure and the rectum Only vague conjectures are available concerning the exact nature of the stimuli which incite en cystation and excystation

Morbid Anatomy —The primary lesions are confined to the large bowel in long standing cases ulcerated areas may be found throughout its entire extent Occasionally the lesions extend from the cecum into the appendix Rarely in advanced cases inva sion of the lowest portion of the ileum has occurred Experiments upon lower animals indicate that the ileocecal valve affords con siderable mechanical protection to the ileum against migration of amebae from the cecum Bacillary dysentery produces an acute dif fuse inflammation while in amebic dysen tery even in advanced cases islands of normal mucosa are found in the affected areas

The amebae are able to injure and pene-trate the normal mucosa and then rapidly invade the submucosa Microscopically amebae are seen in great numbers It seems probable that they often invade the blood vessels and are frequently carried to the liver but that only a small proportion are able to gain a foothold and set up hepatic lesions The lesions of the liver vary in detail Mul tiple abscesses may occur but often a soli tary abscess is found which may ultimately attain a relatively enormous size and rup ture into the peritoneal cavity or through the diaphragm into the lung *E histolytica* is the only pathogenic micro organism which is constantly present in the lesions but the invading bacteria influence the character of the contents of the abscess and modify the reaction in the surrounding tissue Lique faction of the contents may be delayed thus rendering difficult the attempt to locate an abscess by aspiration The amebae are found in the granulation tissue comprising the wall of the abscess and not in the necrotic cen ter Consequently they are not seen in the pus which is drawn off at operation but after a few days they make their appearance in the discharge from the granulating wall

Symptoms —The *incubation period* is variable and difficult to estimate As deter mined experimentally in man amebae ap-pear in the stools often within four to six days after the ingestion of cysts but the development of symptoms is very irregular Of eighteen volunteers parasitized with his tolytica only four developed dysentery, the symptoms appearing at twenty, fifty seven eighty seven and ninety five days after the infective feeding

The *onset of symptoms* may be sudden or gradual The bowel movements are accom panied by a moderate degree of tenesmus and abdominal discomfort There is usually no nausea and the appetite remains unaf fected If the patient is untreated the symp toms may subside more or less completely in a few weeks only to reappear again In deed a history of intermittent attacks of dysentery at once directs suspicion toward an amebic infection These untreated pa tients may become carriers but more com monly a chronic diarrhea develops The in vading bacteria eventually play a prominent part in the symptoms Periods of low fever and leukocytosis appear from time to time The patients become anemic and emaciated and are slowly but steadily exhausted in the course of years Fulminating cases have oc curred in which bacterial complications ap-pear to be responsible for signs of marked toxemia or even for perforation of the in testine whereas the usual course of the dis ease is slow giving ample time for the for mation of adhesions

Complications and Sequelae —With the improvement in diagnosis and treatment in vasion of the liver has become less common Abscess of the liver has been noted in car riers who have never showed any intestinal symptoms and also in patients long after the intestinal symptoms have subsided Sec ondary metastatic infection of other viscera has been observed for example the develop-ment of abscesses of the brain and spleen Armitage found reports of forty eight cases of brain abscess in the literature

Mixed infections with bacillary and amebic dysentery may occur but are not common The author has on several occasions seen amebic dysentery develop during an attack of typhoid fever

In the healing of extensive lesions of the

ent host the cockroach An International Commission appointed for the consideration of nomenclature turned to other fields and exceeded its purpose by attempting to analyze the generic classification of these amebae but without adequate reference to protozoological material or to representative literature With this limited information the Commission in violation of the International Code recommended that the genus *Entamoeba* be suppressed and the species *histolytica* and *coli* of man be transferred to the distant genus *Endamoeba* of a cold blooded host the roach This opinion has been ignored except in much of the literature from this country where the designation of *Endamoeba histolytica* is often employed Dobell has discussed the situation fully and with fairness to all concerned This textbook in all of its editions has adhered to the acceptable designations *Entamoeba histolytica* and *Entamoeba coli*

Etiology—Of the many genera and species which have been described *Entamoeba histolytica* is the only clearly established pathogenic ameba of man *E dispar* of Brumpt has not been fully accepted as a new species distinct from *E histolytica* The parasitic but nonpathogenic group includes *E coli* *Endolimax nana* *Iodamoeba butschlii* and *Dientamoeba fragilis* Cysts of nonparasitic amebae occasionally pass mechanically through the intestine without colonizing In earlier years some of these species caused confusion but it has been clearly established that they are entirely without etiologic significance These forms are easily detected by cultivation on a nutrient poor medium but not by procedures which are suitable for *Entamoebae*

By experimentation on man Walker and Sellards demonstrated that *E coli* is non pathogenic but it is parasitic and readily establishes itself in the intestine When passed in the feces it does not multiply in nature The pathogenic form *E histolytica* was fed to twenty volunteers eighteen of whom become parasitized and four of these eighteen contracted typical dysentery The fourteen remaining individuals developed no symptoms It is clear from this experiment and from subsequent observations that a considerable number of individuals become carriers of *E histolytica* without the appearance of any symptoms of dysentery These persons are conveniently designated as *contact* or perhaps better as *symptomless carriers* by way of distinction from the *convalescent carriers* who have recovered from clinical symptoms The distinction may at times be a difficult one especially if it is based only on the patient s history

As early as 1875 Losch infected lower animals with *Entamoeba histolytica* and produced a typical acute dysentery Amebic dysentery sometimes develops spontaneously in lower animals, particularly in dogs The more important features of the human disease including abscess of the liver can be reproduced in kittens Clinically and experimentally the course of an infection indicates that *E histolytica per se* does not induce toxic manifestations, in a large measure fatal results are attributable to bacterial invaders The observation of Schaudinn that *E coli* readily parasitizes young kittens remains unconfirmed

The cultivation of *E histolytica* was accomplished by Cutler but dependable methods were first introduced by Boeck and Drbohlav Extensive improvements were developed by Cleveland and Collier who recommended slants of a liver infusion agar or Loeffler's blood serum covered with a 1 to 6 dilution of horse serum in saline

Epidemiology—Amebic dysentery is usually regarded as an endemic disease of tropical and subtropical climates but it has also established itself in the colder parts of the temperate zones Under natural conditions the cases occur sporadically the mode of transmission not being favorable for the development of epidemics With the artificial aid of man explosive outbreaks have occurred such as the one which developed during the exposition of a Century of Progress at Chicago in 1933 Ordinarily the incidence of infection in a community is built up gradually and many surveys have been made to determine the percentage of carriers Thus the examination in Philadelphia of 1060 healthy college students revealed the presence of *E histolytica* in about 4 per cent

The trophozoites and the cysts of *Entamoeba histolytica* are excreted in the feces but no multiplication takes place outside of the host The trophozoites degenerate rapidly and if ingested by man they are easily destroyed by the digestive fluids The cysts are much more resistant and are the means of transfer of the infection from person to person On being ingested with drinking water or with food they readily set up infections either with or without the appearance of symptoms Excystation occurs

crons) than either of the two entamoebae just described and the nucleus contains a mass of chromatin arranged in a large eccentric karyosome The typical cyst is ellipsoidal in form and contains four nuclei The morphologic details are brought out clearly and beautifully in preparations stained with Heidenhain's hematoxylin Cultures are valuable as an accessory aid in diagnosis Under ordinary circumstances it is quite unnecessary to subject the patient to the discomfort and inconvenience of proctoscopic examination either for diagnosis or for the purpose of following the effects of treatment

Prognosis —A patient developing an acute dysentery is in the main fortunate if the diagnosis of amebiasis is established Under early and adequate treatment the outlook for complete recovery is very good In neglected cases of many years duration accompanied by secondary bacterial infection there may be little hope for restoration to full health

Prophylaxis —There is no method of specific protection against amebic infection Personal measures depend upon the usual hygienic precautions

Treatment —The patient need be at rest in bed only during the stage of acute symptoms The *diet* should be bland but the amount may be liberal Drugs are available in considerable variety for specific treatment

Emetine and Its Derivatives —For specific treatment compounds of emetine have been prepared for oral use and for intramuscular injection Emetine bismuth iodide contains about 30 per cent of emetine and it is almost insoluble in neutral or acid solution but dissolves readily in the alkaline contents of the duodenum Three grains (0.2 Gm) contained in an *ordinary* gelatin capsule are given by mouth at bedtime for twelve consecutive nights Notwithstanding its extremely slight solubility in the gastric contents some nausea and even vomiting may follow its administration If necessary tincture of opium may be used to control the nausea Emetine hydrochloride by intramuscular injection is the treatment of choice when lesions of the liver have developed The customary dosage is 1.5 grains (0 1 Gm) daily for a period of twelve days The blood pressure should be taken before the administration of emetine is commenced The earlier signs of toxic action consist in a fall of blood pressure and irregularity in cardiac action Diarrhea may develop as a puzzling complication the appearance of peripheral neuritis is a serious sign The margin between the toxic and the therapeutic dose of emetine is small It is excreted or detoxified with extreme slowness and tends rather to become fixed in the tissues A rest period not of several weeks but preferably of several months is demanded theoretically before repeating a course of treatment Infection with amebae as well as treatment with emetine may produce serious symptoms and the exigencies of a situation may require proportionately larger doses with repetition after a rest period of perhaps only a few weeks

Carbarsone has established itself as the chemotherapy of choice for amebic infection of the intestine Emetine may be used for refractory cases of amebic dysentery for the patient for whom arsenicals are contraindicated and for the treatment of amebic hepatitis

Arsenicals —Carbaminophenylar onic acid (carbarsone) was introduced clinically by Reed and his associates The administration is simple for adults 4 grains (0 25 Gm) is given twice daily by mouth for ten days Toxic manifestations appear to be rare and relapses less frequent than after emetine The proportion of relapses is inevitably higher in neglected patients who have received no treatment until after the infection is thoroughly established It is desirable to avoid the use of arsenicals in patients showing impaired function of the liver or kidney

The clinical results obtained by the use of emetine or carbarsone are often striking However these drugs do not lend themselves in a reliable manner as a therapeutic test for the diagnosis of dysenteries of doubtful etiology

Castela nicholsoni contains an active principle probably a glucoside which is of distinct value in the treatment of amebic dysentery Unfortunately reliable preparations of this plant are not available commercially

The *halogenated oxyquinolines* (chiniofon and vioform) have enjoyed some measure of success but they have not yet established themselves in routine practice

intestine the excessive formation of scar tissue sometimes leads to partial obstruction A child of fourteen years with a giant colon, who was thought for a time to have Hirschsprung s disease, proved ultimately to have an amebic infection of about nine years' standing

Immunity—An acute attack of amebic dysentery affords no protection against subsequent infection Relapses are the rule in an infection of the intestine whereas an amebic lesion of the liver when once healed shows no tendency to recur Encystment of *E histolytica* does not take place in the liver or other tissues

Diagnosis—The history of the patient may be helpful At the onset of an amebic infection the dysentery is often intermittent in character in contrast to the continuous symptoms usually seen in the bacillary types and in chronic ulcerative colitis Eventually in the amebic cases the remissions tend to become less marked Physical examination of a patient with moderate symptoms reveals little except abdominal spasm and tenderness over the affected portions of the bowel The temperature and the pulse rate may be normal or slightly elevated

The possibility of involvement of the liver must be remembered An abscess high in the dome may produce few physical signs An advanced lesion may lead to weakness and anorexia, the development of fever and leukocytosis accompanied sometimes by chills and sweating X ray plates seldom reveal an abscess but fluoroscopy sometimes shows limitations of motion of the diaphragm Exploratory aspiration is commonly practiced The presence of pleural pain with some dulness on percussion and the successful aspiration of pus have led to the erroneous diagnosis of an empyema

The symptoms produced by *E histolytica* a highly organized protozoon are imitated rather closely by the simple bacillary infections In the acute stage the chief difference is seen in the toxemia characteristic of the Shiga type of bacillary dysentery In the differential diagnosis one must take into consideration the intestinal symptoms which arise in diseases such as schistosomiasis tuberculosis carcinoma and even syphilis of the rectum Erroneous diagnoses in various parts of the country were a serious factor in the case of some of the patients whose infection originated in Chicago

Microscopic Examination—In the differentiation of bacillary and amebic dysentery the general character of the stools should be noted In acute bacillary infections the fluid stools contain but little fecal matter a moderate amount of mucus and often considerable blood which may be partially laked Microscopically many pus cells are seen together with large and small mononuclear cells The nuclei of these cells are rich in chromatin and may be seen in the unstained smears in contrast to the small chromatin poor nucleus of *E histolytica* In amebic cases the stools usually contain considerable fecal matter mixed with blood and mucus and the cellular exudate is less abundant In countries where bacillary dysentery of the Shiga type is prevalent a prompt provisional diagnosis permits early treatment with serum without waiting for the completion of the bacteriologic examinations

The rapid degeneration of the motile forms of entamoebae in stool specimens require entirely fresh material for examination The distinction between *E histolytica* and *E coli* concerns the field of protozoology The motile forms measure approximately 20 to 30 microns and they are not strikingly different in their appearance The nucleus of each is small in proportion to the size of the cell and very poor in chromatin *E histolytica* presents evidence of greater motility The ectosarc is clear and hyaline phagocytosis is active the amebae often being filled with red cells but seldom with bacteria *E coli* is usually sluggishly motile and freely ingests bacteria but seldom contains red cells since ordinarily none are available There is on record 1 authentic instance in which *E coli* in the presence of a bleeding papilloma of the sigmoid ingested red cells in moderate numbers In typical cases the differentiation of the trophozoites of the two species is easy in borderline cases it may be very difficult The cysts of *E coli* are fairly large (approximately 15 microns in diameter) and typically contain eight nuclei The cysts of *E histolytica* vary in size (7 to 15 microns) and typical forms contain four nuclei Super and subnucleated forms of both species occur *Endolimax nana* in its vegetative stage is smaller (10 mi

of malaria is low and is largely limited to the southeastern states and the Mississippi River basin there are nearly 1 000 000 cases with 5000 deaths

Etiology —The specific etiologic agent of malaria is a unicellular organism which lives at the expense of the red blood corpuscles in certain reptiles birds and mammals and belongs to the order of *Hemosporidia* class *Sporozoa* and the single genus *Plasmodium* The species within the genus are not numerous and they are capable of producing infections only in hosts that are closely related In man malaria is produced by four specific parasites known as *Plasmodium vivax P malariae P falciparum* and *P ovale* There are certain similarities but each has distinct morphology and definite pathogenicity and none of them has been found to be infectious for any of the lower animals Unlike virus or bacterial diseases the etiologic agent of malaria has not been successfully cultivated on an artificial medium nor in the presence of living cells outside its respective host The only means of transmission in nature is by anopheline mosquitoes although different species act as vectors in different parts of the world The anopheline mosquito does not act as a mere mechanical transmitter of the pathogen from man to man but serves as a haven where the parasite undergoes a definite development necessary for the perpetuation of the organism An artificial method of transmission is the hypodermic syringe commonly used by drug addicts which results in the actual transfer of infected blood from a carrier to a susceptible person This type which occurs more often in the larger cities is responsible for many deaths as it is usually the highly virulent falciparum malaria Less frequently malaria is acquired in nonendemic areas following transfusions from an infected donor There are many authenticated reports of this occurrence where children have become infected from parent donors who last had symptoms twenty or more years previously It is interesting to note that in practically all such instances the causative agent has been *P malariae*

The Mosquito Host—Many different species of anopheline mosquitoes have been described from various parts of the world Although most of them can transmit malaria they vary enormously in their susceptibility In North America *Anopheles quadrimaculatus* has been shown to be the only important vector The habitat of this mosquito extends to the southern border of Canada but the severe winters in addition to agricultural drainage and clearing have largely limited its activity as a disease carrier to the southern states The adult anopheline mosquito is identified by its spotted wings and its habit of resting at an angle Only the female mosquito can become infected as she requires a blood meal to produce fertile eggs The male is not bloodsucking Anopheline mosquitoes lay their eggs in swamps ponds and streams and the larvae lie and feed horizontally on the surface of the water a characteristic which makes them more liable to destruction by floating larvicides particularly oils and Paris green The common pest mosquito Culex lays its eggs in caves tin cans cisterns or any container of water in and about houses The larvae hang head downward with an air siphon sticking above the surface of the water and the body of the adult is parallel to the surface of its resting place It is not concerned with the transmission of malaria and is definitely a domestic mosquito while the anopheline prefers a wilder environment

Development of the Malaria Parasite in the Mosquito—In order to become infected a female mosquito must first bite a person that has male and female malaria parasites in the circulating blood as the asexual parasites cannot survive in the mosquito s stomach The sexual forms known as gametocytes initiate the cycle of development within the stomach of the mosquito where they undergo fertilization This is accomplished by the male parasite pushing out several flagella which break loose and come into contact with the female form Many attempt to penetrate but when one succeeds the foiled ones depart for other quarry (This also can be observed readily under the dark field microscope) The fertilized forms then push their way out between the stomach cells and form cysts on its outer wall These cysts known as oocysts gradually enlarge so that by the eighth or tenth day they are mature and measure about 75 microns in diameter If examined under the microscope the oocysts will be seen to be

Craig states that emetine hydrochloride should not be employed as a curative drug in amebic dysentery, but should be used only for the control of severe diarrhea or dysentery in patients presenting these symptoms After this a course of carbarsone, chiniofon or some of the other amebacidal drugs should be instituted

Relapses —The patient must be observed carefully for the appearance of recidives After apparently successful or even brilliant results amebae may be found in the feces within the first week after the cessation of treatment

The question of surgical intervention inevitably arises when neglected cases with extensive secondary infection fail to respond to medical treatment The most satisfactory type of operation is an ileostomy or colostomy without using any subsequent irrigation thus permitting the large bowel entire rest

Liver Abscess —Of the many drugs recommended for amebiasis, only emetine is suitable for treating metastatic infections of the liver and early lesions may heal promptly under its use Such a result is gratifying but there is opportunity for radical improvement in the chemotherapy of this complication When a definite abscess has formed it is altogether desirable to depend on aspiration avoiding if possible any open operation In cases where suitable drainage can be obtained only by radical surgery a mortality of 30 per cent or more may be expected

MALARIA

Definition —Malaria is an infectious febrile disease produced by several species of protozoa belonging to the single genus *Plasmodium* It is transmitted naturally from host to host only by the bite of an infected anopheline mosquito In the mosquito the development of the parasite is observed on the stomach wall and in the salivary glands while in man it is continued in the red blood corpuscles Clinically the disease is characterized by paroxysms of severe chills fever and sweating These paroxysms may occur daily (quotidian), on alternate days (tertian) or with an interval of three days between chills (quartan) After recovery from the acute attack the disease has a tendency to become chronic with occasional relapses

History —Historically malaria is an ancient disease as some of the earliest records of man show that it was recognized as a definite clinical entity In the fifth century B C Hippocrates differentiated the fever into quotidian tertian and quartan types Little or no light was thrown on the disease from that time until 1880 when a French army surgeon by the name of Laveran recognized the pigmented parasites in the red cells of a soldier in Algiers and was convinced that they were the cause of malaria Soon all the different asexual stages of the parasites were recognized in the red cells In 1897 MacCallum saw the fertilization of a female gametocyte following the exflagellation of a male parasite and correctly assumed that the malaria parasite had a sexual and an asexual cycle The incrimination of the mosquito as the vector for malaria followed the work of Theobald Smith who was the first to discover the arthropod transmission of disease when the tick was shown to be the essential intermediate host in Texas cattle fever English and Italian workers quickly applied the same principle to malaria and found certain anopheline mosquitoes were infected and responsible for the transmission in man By 1900 the details of the cycle in man and mosquito were known and the highly specialized manner by which this disease propagates itself was understood This complete information in addition to the long known efficacy of quinine as a treatment, led many to believe that malaria would soon be eradicated, but forty years later this belief remains far from realization

Malaria at the present time is one of humanity s chief scourges and there are many fertile areas that remain uninhabitable because of its influence It is probable that the combined number of deaths in all parts of the world where malaria exists amount to almost 2 000 000 annually In India the figures of the annual malaria survey show that there are approximately 100 000 000 cases with 1 000 000 deaths Even in the United States where the endemic prevalence

attack young and old red cells indiscriminately

Plasmodium ovale first described in 1923 by Stephens and now generally accepted as a definite species derived its name from the fact that the infected red cell always assumes an oval shape Otherwise its morphology and behavior are practically identical with those of *P vivax*

Morbid Anatomy —Tertian and quartan malaria rarely come to autopsy except as a contributory cause of death The pathologic lesions in these instances are in the main due to the disintegration of parasitized red cells and the accumulation of pigment In the spleen one finds the maximum evidence of an active or latent malaria infection and because of the collection of pigment no other disease presents a more pronounced pathognomonic picture either macroscopically or microscopically The spleen is usually markedly enlarged slate gray in color and of soft consistency during the acute disease The capsule is smooth tense and may even rupture spontaneously The cut surface exudes a brownish pulp and the malpighian bodies stand out Microscopically the sinuses are distended with parasitized and normal red cells The macrophages are laden with parasitic debris which is mostly pigment

The liver is usually somewhat enlarged and slightly darker than normal The microscopic picture shows the Kupffer cells engorged with parasites in various stages of disintegration There is little or no evidence of toxic degeneration in the parenchymal cells The heart lungs, kidneys and pancreas have a normal cellular structure and the only finding of interest is again the presence of pigment in the active macrophages

Falciparum malaria is responsible for the major portion of deaths due to uncomplicated malaria and likewise presents some pathologic lesions not present in vivax or quartan malaria Fatal cases are usually associated with an overwhelming infection and cerebral involvement The brain shows a gross brownish discoloration of the gray matter with macroscopic punctate hemorrhages in the white matter Stained sections reveal the capillaries filled with parasites in various stages of development The cerebral capillary occlusion shown in Fig 35 which is characteristic of falciparum malaria may also frequently be quite generalized and present a pathologic picture of congestion A pathologist is frequently able to make the correct diagnosis of this disease from a glance at the exposed tissues because of the slate gray tinge due to capillary engorgement with pigmented parasites

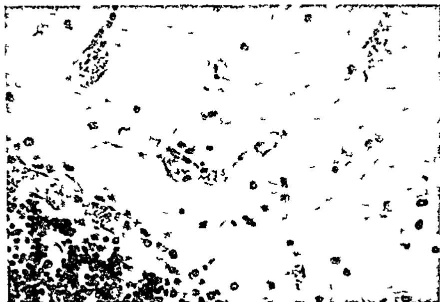

Fig 35 —Malarial parasites occluding cerebral capillaries in falciparum malaria. × 600 (Courtesy of Dr Milton Helpern Bellevue Hospital New York Photograph by J B Haulenbeck)

distended with spindle shaped sporozoites At this time they rupture into the body cavity of the mosquito and the liberated sporozoites make their way to the salivary glands where they lie and await an opportunity to enter the blood stream of a susceptible individual The sporozoites escape from the salivary glands as the infected mosquito bites an individual thus initiating the cycle of development in the human host At this step there is a missing link in the life history of the malaria parasite it was last seen as a spindle shaped sporozoite in the salivary gland of the mosquito and next observed about ten days later as a ring shaped' parasite in the human red blood corpuscle No one has recognized an intermediary form or understood the exact manner in which it attacks the red cells

Malaria Parasites in Man—The most common variety is *Plasmodium vivax* About ten days after an infection has been acquired through the bite of an infected anopheline the first parasites are observed in the red cells as circles of cytoplasm with a mass of red chromatin This stage is commonly referred to as the ring form' There follows a progressive growth of the parasite into an ameboid stage characterized by irregular arrangement of the cytoplasm appearance of pigment granules and enlargement of the chromatin The infected red cell becomes somewhat larger and paler than normal and contains numerous reddish granules known as Schuffner s dots which occur only with this species of parasite As the parasite continues to enlarge the amount of pigment increases and the nucleus starts to divide At the end of forty eight hours the red cell is a mere membrane all hemoglobin has been devoured or replaced by the parasite The nuclear fragments have assumed a rosette form with each unit known as a merozoite which is a daughter parasite As the red cell ruptures the cluster of merozoites usually sixteen in number are released and each attaches itself to a new red cell The cycle is then repeated every forty eight hours but fortunately for man not every merozoite that is released finds its way unhindered to reproduce its full quota of progeny since fully 90 per cent are destroyed by the macrophages located chiefly in spleen liver and bone marrow

For some unknown reason there is a tendency for the vivax merozoite to prefer a reticulocyte to a mature red cell for initiating its development The asexual reproduction of the parasite continues for several days when new forms appear and they are the sexual ones (gametocytes) They fill the entire red cell Their pigment is scattered and chromatin is diffuse The male parasite may be differentiated from the female by its very pale staining cytoplasm with Giemsa or other Romanowsky stains The gametocytes are concerned only with infection in the mosquito have no clinical importance and usually persist in the blood in limited numbers for two or three weeks The characteristics which differentiate *P vivax* from other parasites are a forty eight hour cycle sixteen merozoites in the mature parasite at time of segmentation, and an enlarged pale, parasitized red blood cell usually stippled with red staining granules

Plasmodium malariae which produces quartan malaria in man requires seventy two hours to complete each asexual cycle in the red cell Except for its slower metabolic activity this parasite bears a close similarity to the behavior of *P vivax* Morphologically the young parasite is frequently observed as a band form across the red cell The parasitized red cell seems to have a greater concentration of hemoglobin and is somewhat reduced in size There are usually only eight merozoites in the mature parasite and after segmentation they prefer to attach themselves to mature red cells rather than the younger reticulocytes

The asexual cycle of *Plasmodium falciparum* is first recognized as an extremely small signet ring in the red cell approximately one half the size of a *P vivax* ring Only in the severest cases are the more mature stages of the parasite seen in the red cell The reason for this seems to be that early in the acute infection there is a tendency for the ring forms to aggregate in the capillaries throughout the body where they undergo their usual development The required time for one cycle is not definitely known but is probably between twenty four and forty eight hours The gametocytes are crescent shaped a definite diagnostic finding as no other known malaria parasite has this morphology The parasite seems to

period which may vary from eighteen to forty days The onset is similar to that of vivax malaria being initiated by a low grade remittent fever lasting from three to five days and without chills The paroxysms usually occur every seventy two hours the time required for the complete development of the asexual cycle in the blood However counting from the beginning of the day of one chill to the end of the day of the next four days are required (Fig 37) which accounts for the unfortunate name quartan malaria A double quartan infection gives a chill on two consecutive days with an intervening day of normal temperature Rarely *does one encounter daily chills with quartan* malaria When compared to vivax malaria the paroxysm lasts longer is slightly more severe and the patient feels less like getting up between chills

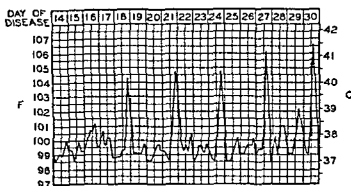

Fig 37—Temperature chart of a patient with quartan malaria

Falciparum Malaria—Falciparum or estivo autumnal malaria is a more severe disease than the others and as such is responsible for the origin of the purely descriptive terms of the disease as cerebral algid hemorrhagic pernicious and many others The latter refer to symptoms which depend largely upon the localization of the parasites The incubation period is commonly twelve days the fever is irregular and not characteristic The paroxysms are similar to those accompanying other malarias although of longer duration and occurring at more irregular intervals The temperature is usually high If there is a cerebral localization of the parasites the onset is rapid with delirium or coma and death frequently ensues without a return to consciousness The disease may present a gastro intestinal syndrome with abdominal cramps diarrhea vomiting and only a few parasites in the blood The patient is markedly dehydrated and may have a high or low grade fever Stools may contain blood resulting from intestinal capillary thrombosis and ulceration

Hemoglobinuria is frequently associated with falciparum malaria where the hemolysis of red cells is the prominent feature of the disease The urine may be tinged with hemoglobin or it may be almost black with a heavy amorphous precipitate The chills are severe the patient exceedingly ill and parasites are usually infrequent or absent from the blood stream In fatal cases the urine becomes scanty and finally is suppressed entirely

Diagnosis—An absolute diagnosis of malaria depends upon the recognition of the parasite in stained thin or thick blood smears Ordinary thin smears should be made on slides that have been thoroughly cleaned to insure even spacing of the red cells They can be stained with Giemsa s Wright s or Hastings stain For the uninitiated the thin smear method is preferred because there is less opportunity to be confused by artifacts It is easy to overlook parasites by this method however although they may be present in sufficient numbers to produce clinical activity The thick smear method is advantageous because it affords a means of concentrating the blood The thick film should be about the size of a dime on a very clean slide The two preferred methods of staining are with Giemsa s or Field s The former is satisfactory and is accomplished by adding one drop of Giemsa to 1 cc of

Symptoms—The symptoms of malaria vary according to the type of parasite producing the disease as each of the four parasites has a characteristic behavior and time of sporulation which give rise to different clinical pictures Symptoms also vary according to host resistance or immunity For example in areas of high malaria endemicity people may go about their work with no apparent difficulty and have at the same time a considerable number of circulating parasites in their blood stream Less intense infections gauged by the number of circulating parasites will completely prostrate a nonimmune individual coming into the same area There is evidence to show that strains of the same species of parasite may also have different virulence However the initial infections in susceptible individuals have certain classic features according to the species involved

Vivax or Tertian Malaria—This is by far the most common the mildest and most likely to recur Because large numbers of individuals have received the beneficial effects of vivax malaria acting antagonistically against general paresis of the insane excellent opportunities have been afforded for observing the symptoms in great detail The most thoroughly studied malaria infections were induced by the bite of infected mosquitoes and once established they were allowed to run their full course in order to obtain greatest therapeutic results On about the sixth day after the bite of the mosquito the patient has a mild backache muscle soreness and a low grade prodromal temperature without chills Paroxysms appear on about the fourteenth day Usually these paroxysms occur on alternate days and coincide with the segmentation of the mature parasite although they may occur daily (quotidian), which means that there are two broods of the same parasite, one segmenting on even days and the other on odd days of the disease or the two types may occur during the course of the one infection as shown in Fig 36 A typical paroxysm for vivax malaria consists of a cold hot and sweating" stage

Cold Stage—The patient has a chilly sensation over the entire body which gradually increases in intensity the teeth chatter the skin becomes blue and cold and there is an uncontrollable shaking In spite of heat pads and blankets it is impossible to keep the patient warm The pulse is rapid and weak and occasionally there is nausea and vomiting The cold stage lasts on the average of one hour and it subsides as the body temperature rises

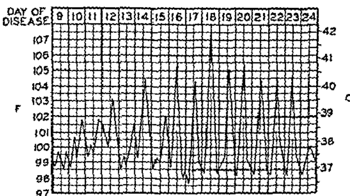

Fig 36—Temperature chart of a patient with vivax malaria showing both tertian and quotidian types of fever (Photograph by J B Haulenbeck)

Hot Stage—In this stage the patient has a flushed face severe headache and may be partially delirious with a temperature often as high as 107° F There is a sensation of intense heat with a hot dry skin and this portion of the paroxysm lasts about two hours

Sweating Stage—The sweating stage is ushered in with an abrupt onset and the patient breaks out into a profuse perspiration Temperature drops to normal the headache disappears and a feeling of well being comes over the patient Although somewhat drowsy and weak he feels able to resume work

Quartan Malaria—This parasite produces an infection after a prolonged incubation

to demonstrate specific protective and complement fixing antibodies and agglutinins in the serum of experimental animals after recovery from the acute attack The chief defense of the body against an acute malaria infection or recovery from a relapse probably depends upon a greatly accelerated rate of phagocytosis by the individual macrophages of the reticulo endothelial system

Prophylaxis —It is particularly advisable to give soldiers prisoners laborers or similar groups of personnel quinine or atabrine as a prophylactic drug where malaria is heavily endemic and where the predominant type is falciparum malaria There is as yet no known drug that will prevent the occurrence of malaria infection although both quinine and atabrine will usually prevent the development of clinical malaria as long as either drug is administered As far as their effectiveness is concerned they are comparable The prophylactic dosage of quinine is 0.3 Gm (5 grains) per day given as long as the subject resides in the infected area although some advise as much as 0.5 Gm (7 grains) The dosage of prophylactic atabrine is 0 1 Gm (1½ grains) given on alternate days

Treatment —The accepted treatment for malaria is the administration of certain chemotherapeutic drugs Specific antiserum from animals or serum from convalescent humans has not proved beneficial in the prevention or treatment of the disease Although the assertion is repeatedly made that malaria is a disease for which there are specific therapeutic drugs and that it is a simple matter to overcome the infection the fact remains that malaria is a most difficult disease to eradicate completely This is evidenced by the frequent relapses which occur after therapeutic measures considered adequate in patients who have had no opportunity to become reinfected

For many years the standard treatment of malaria has consisted of 3 Gm (45 grains) of quinine daily for one week and then 0 6 Gm (10 grains) daily for eight weeks This routine has been discarded by many because of the difficulty of inducing the patient to continue treatment for two months and because no assurance of cure could be offered Knowledge that relapses occur in spite of therapy but that they are almost always less severe and more responsive to treatment than the initial attack has brought about a new concept in malaria therapy Now the rationale is not to attempt the difficult task of eradication of the infection in one step but to bring the acute attack under control and be prepared for and treat the relapses as they occur

In addition to modification of quinine administration for malaria recent advances in therapy have been made with atabrine and plasmoquin two synthetic drugs effective against the malaria parasite Therefore at the present time there are three accepted antimalarial drugs which may be used or substituted in certain instances because of their selective action In order to determine as nearly as possible the best treatment for the individual with malaria the Malaria Commission of the League of Nations in 1937 arranged for outstanding malariologists to conduct experiments arranged beforehand on the prophylaxis and chemotherapy of malaria involving over 12 000 individuals throughout various parts of the world Their conclusions and recommendations are in agreement with those of others actively interested in the subject In general the results showed that in ordinary cases of vivax or quartan malaria it is immaterial whether quinine or atabrine is employed for the treatment of the acute attack Atabrine seems to have a distinct advantage in falciparum malaria Plasmoquin has the tendency when given with quinine or after atabrine to reduce the number of relapses which usually follow vivax or quartan malaria and is effective against the gametocytes of all three infections especially those in falciparum malaria The most successful therapeutic results will come from the proper choice of drug and with any infection it is imperative that the physician be in a position to diagnose and follow the treatment with the aid of a microscope As there is a choice the indication contraindications and method of administration for each drug are discussed separately

Quinine—The oral administration of quinine salts is advised whenever possible and should be given parenterally only when the patient is in coma or vomiting profusely Because of the shortage of quinine and because of the more rapid effect of quinine on falciparum malaria it is beneficial to give

distilled water and staining for thirty minutes *Field s method* has been recently discovered and possesses many advantages, long drying of the film is unnecessary, the entire staining takes less than ten (10) seconds and there are fewer artifacts (Consult J W Field *Trans Roy Soc Trop Med* 35 35 1941) The greatest number of parasites appear in the blood stream immediately after the chill and for the following six hours The inability to find parasites in blood films does not rule out malaria, particularly in subsiding or chronic infection Splenic puncture for diagnostic purposes is unwarranted and dangerous as it may lead to the rupture of an enlarged tense spleen The chief complaint of the patient is usually a severe chill, high fever and sweating In the history there also is usually information showing that malaria is endemic where the patient resides or that he has traveled in infected areas for example, campers and hunters frequently acquire malaria in this manner

There are few physical signs The patient appears anemic the degree varying according to the duration and severity of the disease The spleen if sufficiently enlarged to be palpated is soft in the acute disease and firm in chronic cases

There is a therapeutic diagnostic test of giving quinine to a suspect having negative blood smears and elevated temperature which is very useful if correctly interpreted It is strong evidence if the drug fails to reduce the fever that the cause is not malaria Likewise it is extremely important that the physician ascertain whether the patient has taken some remedy on his own initiative before seeking medical aid This self medication is a common practice and accounts for a temporary cessation of symptoms and disappearance of parasites from the blood stream

In addition to the diagnosis of the individual the physician is frequently called upon to determine the prevalence of incidence of malaria in a community The established routine is to obtain the parasite rate by blood smear examination from as many individuals as feasible At the same time a determination of the number of enlarged spleens and the degree of splenomegaly furnishes additional information Personal history about malaria infections in previous years is also included Such a survey will give data necessary to express quantitatively the amount of malaria in a community and if continued will furnish a guide to yearly endemicity of the disease

Prognosis—Patients with vivax or quartan malaria rarely, if ever succumb unless complicated with other diseases malnutrition, or exposure Even in endemic areas where many infections are self treated deaths are few Also in paretics where malaria has been induced for therapeutic purposes and allowed to run a full course without intervention, the death rate is almost nil Vivax and quartan malaria are diseases of high morbidity and low mortality

Falciparum malaria is the cause of practically all deaths due to malaria but if recognized early usually lends itself to therapy A guarded prognosis must be held for patient with the cerebral type in coma or stupor Malaria and hemoglobinuria always present a grave prognosis

Relapses are to be expected with all types of malaria These may occur at any time but are most likely to occur after exposure change of climate hemorrhage, or when body resistance is lowered from any cause

Immunity—A malaria infection confers a low grade but specific immunity upon its host after the acute attack has subsided This acquired immunity in man is of short duration as an individual may have repeated attacks produced by the same organism within a relatively short space of time In experimental animals the residual immunity following complete eradication of the infection persists only a few weeks It is held by many that a host is immune to malaria only in the presence of infection There is no cross immunity in human malaria as it is frequently observed that a person may have a simultaneous infection with two or more types of malaria It is highly probable that an individual is resistant only to the malaria in his particular locality for example it has been shown that a person immune to a strain of vivax malaria in Florida behaves as a normal when exposed to infection from a vivax parasite from Cuba

The mechanism of immunity in malaria is not clearly understood but it is possible

is to be avoided at all costs because it removes the body's chief organ of defense

TRYPANOSOMIASIS

AFRICAN TRYPANOSOMIASIS

(*Sleeping Sickness*)

MOST investigators recognize two distinct varieties of trypanosomiasis in Africa—Gambian and Rhodesian sleeping sickness—although recently some feel that the causative agent of both may be physiologic variants of the same trypanosome Both are limited to tropical Africa The Gambian type is irregularly distributed over an enormous area and because of the habits of its insect vector *Glossina palpalis* follows water courses It is found on the west coast from Senegal southward to Angola and extends eastward from Bahr el Ghazal Lake Albert and Lake Victoria on the north to Lake Banguelo in the south The Rhodesian type is limited to a much smaller area occurring only in portions of Nyasaland Rhodesia Tanganyika Territory and Portuguese East Africa

Gambian Sleeping Sickness —The Gambian disease is caused by *Trypanosoma gambiense* For a description of this parasite as well as of trypanosomes in general the reader is referred to standard works on protozoology Suffice it to say here that *Trypanosoma gambiense* is a typical polymorphic mammalian trypanosome which varies in length from 10 to 39 microns and possesses a spindle-shaped body which moves sinuously because of its undulating membrane and free flagellum It reproduces by longitudinal fission and so far as is definitely known retains its trypaniform structure throughout its life cycle in man Transmission from man to man is effected by the tsetse fly *Glossina palpalis* After the fly has become infected by ingesting blood from an infected human being the parasites undergo a definite developmental cycle which lasts twenty days or more Eventually they invade the salivary glands where once established they constitute a constant source of infection when the fly bites uninfected persons Occasionally transmission may take place mechanically by means of *Glossina* or other biting insects or by coitus

In man the trypanosomes are found chiefly in the blood vessels and lymphatics They may however invade the connective tissue and the parenchyma of the various organs a fact which may, indeed account for the tissue lesions

The length of the incubation period has not been accurately ascertained but is probably much shorter than was originally supposed Initial symptoms have appeared in some cases fourteen days after inoculation The disease itself generally passes through two stages the first being sometimes known as the *trypanosome fever stage* and the second as the *sleeping sickness stage* The first is characterized principally by irregular attacks of fever chronic polyadenitis exanthemata frequency of the pulse and respiration and asthenia the second by exaggeration of the symptoms of the first stage marked emaciation and by the appearance of nervous symptoms tremors incoordination of movements paralyses mental disturbances apathy somnolence coma and death These two stages are as a rule not clearly delimited but merge into one another the second stage gradually manifesting itself as the nervous symptoms develop following injury to the nervous tissue from the inflammatory changes in the lymphatics of the brain and spinal cord (Blacklock and Yorke)

Rhodesian sleeping sickness is caused by *Trypanosoma rhodesiense* In the human host the morphology of the species is identical with that of *Trypanosoma gambiense* In subinoculated small laboratory animals however the nuclei of a varying percentage of the short forms migrate posteriorly to the

1 Gm (15 grains) of quinine daily in doses of 0 3 Gm (5 grains) each for two days and then follow immediately with a course of atabrine described below A complete course of quinine consists of 1 Gm (15 grains) daily for seven days in divided doses of 0 3 Gm (5 grains each) This usually suffices to eliminate all parasites from the circulating blood in cases of vivax and quartan malaria In *falciparum malaria* the effective dose is somewhat larger, 0 3 Gm (5 grains) four times daily for seven days In any instance therapy should not be discontinued until the patient has had five days of normal temperature with negative blood smears for the same period of time The patient should then be advised that this may constitute the final treatment but that a certain percentage of individuals will experience a relapse which in practically all instances is less severe than the initial attack The treatment for the relapse is the same as for an initial attack The appearance of a malaria attack following treatment is not always a relapse but may represent a reinfection with a different parasite This being especially true in regions where malaria is endemic emphasizes the necessity for microscopic diagnosis For patients unable to tolerate quinine by mouth it should be given intravenously as quinine di hydrochloride in very dilute solutions 0 3 Gm (5 grains) in 10 cc of sterile distilled water Ringing of the ears dizziness or slight deafness following quinine do not constitute symptoms of alarm but a real idiosyncrasy is recognized by an immediate urticarial rash dyspnea or cyanosis and warrants immediate withdrawal of the drug

Atabrine—Atabrine is a synthetic drug and a quinoline derivative Its use is indicated in vivax and quartan malaria but is especially efficacious against the *asexual* parasites of falciparum malaria A course of treatment of atabrine consists of 0 1 Gm (1½ grains) three times a day for five days Whenever possible it should be given by mouth With this treatment vivax and quartan malaria respond in practically the same manner so that usually no parasites are found after the third dose Falciparum malaria responds more slowly The parasites may not disappear until after the fourth dose or later and there is little or no effect against the gametocytes of this parasite As a rule fewer relapses occur after atabrine than quinine therapy, although the difference in the results between the two drugs is not marked Where oral medication is not feasible the drug can be given intramuscularly in daily doses of 0 2 Gm (3 grains) Practically all patients develop a temporary yellow discoloration of the skin following its use which is due to deposition of the dye within the tissues and is not to be regarded as a toxic symptom There have been occasional reports of temporary mental derangement following atabrine although this finding is very infrequent There are also reports to the effect that certain preparations occasionally produce nausea and vomiting This complication can be avoided or lessened by taking the drug immediately preceding a meal

Plasmoquin—This synthetic drug has its particular effective action against the gametocytes of malaria infections particularly falciparum malaria It should not be used alone in the treatment of acute attacks of malaria but in conjunction with quinine or following the administration of atabrine When given with quinine it reduces the number of relapses which usually follow vivax or quartan malaria The simultaneous administration of atabrine and plasmoquin is not advised because there is a *tendency* to increase the toxicity of each Therefore when atabrine is the drug of choice plasmoquin should be withheld until the week following Because of its toxicity plasmoquin should be given under the direct supervision of the physician in biweekly doses of 0 0? Gm (⅓ grain) until gametocytes have disappeared

The general treatment consists of simple measures aimed at keeping the patient comfortable especially during the acute paroxysms In infections complicated by vomiting or diarrhea special effort should be made to maintain the normal fluid level It is advisable that convalescent patients receive iron in any of the available forms as it is extremely beneficial in the restoration of the hemoglobin deficiency Many favorable reports have followed the use of liver therapy There are occasional reports advising splenectomy in chronic cases with gross enlargement of the spleen but this practice

are not advised In second stage conditions the doses per kilo of body weight should be increased to 0 09 Gm for children 0 07 Gm for young adults and 0 06 Gm for adults In advanced second stage cases two or three large doses should be given at five-day intervals followed by a rest of ten to fourteen days The maximum dose for adults should be 4 Gm The drug may be given intravenously or intramuscularly The severe toxic reaction is optic atrophy

Orsanine or Fourneau 270 is extensively used in French Equatorial Africa and is believed by the French workers to be equal to tryparsamide which it has partially replaced It is similar to tryparsamide in dosage toxicity and effect on the optic nerve The greater activity of orsanine is believed to be due to the large proportion which is reduced to the active form and not to any greater power of penetration into the cerebrospinal fluid

Neocryl is well tolerated in weekly doses from 2 to 4 Gm Comparatively few patients have been treated with this drug In first stage patients the results compare favorably with tryparsamide but in the second stage cases the results have been unsatisfactory

Germanin or Bayer 205 moranyl known in Great Britain as antrypol and in France as Fourneau 309 is of very great value in the early stages of the disease before involvement of the nervous system probably because of its failure to penetrate readily into the central nervous system The toxic reactions are relatively few transient edema skin rashes pruritus purulent conjunctivitis stomatitis skin rashes and mild peripheral neuritis The drug should be given cautiously to patients with impaired kidney function Bayer 205 may be given intravenously or intramuscularly Various investigators have reported cures after administering a total of about 10 Gm of the drug The exact course of treatment varies with different authorities The usual single intravenous dose for an adult is 1 Gm dissolved in 10 cc of water given weekly for a course of five treatments Some authorities recommend a combined course of germanin and tryparsamide especially in moderately advanced cases

W H TALIAFERRO

SOUTH AMERICAN TRYPANOSOMIASIS

(*Chagas Disease*)

South American trypanosomiasis or Chagas disease is found chiefly in Brazil but has also been found in Guatemala San Salvador, Panama Colombia Venezuela Peru Argentina and Chile The parasite has been found in reduviid bugs in Ecuador Uruguay, Mexico and the United States (California and Arizona) The trypanosome may be primarily a parasite of the armadillo and opossum and only accidentally transmitted to man

Etiology—The causative agent, *Trypanosoma cruzi* when found in the blood has an ordinary trypaniform structure and averages about 20 microns in length The parasites however unlike those of the African types do not reproduce in the blood but invade the tissues and are transformed into typical leishmania like parasites These tissue or leishmaniform bodies are spherical vary from 2 to 4 microns in diameter and exhibit the same structure as the Leishman Donovan bodies found in kala azar or Oriental sore They may be again transformed into trypaniform bodies and reenter the blood The infection is transmitted from man to man or from animal to man by several species of reduviid bugs chiefly *Triatoma megista* The bug receives its infection by ingesting infected blood but whether man is infected by the bite of infected bugs or from the feces of such bugs is not definitely known

Clinical Course—The disease can generally be divided into two stages—acute and chronic The *acute stage* generally lasts twenty to thirty days and is characterized especially in children by fever myxedematous swellings and enlargements of the thyroid and lymphatic glands liver and spleen During this stage the trypaniform parasites are present in the blood and the leishmaniform bodies are found in the tissues If the patient survives this stage the disease becomes chronic and may persist for many years During the *chronic stage* the trypaniform parasites disappear from the blood but the tissue infection with the leishmaniform organisms continues Symptomatically this stage is characterized by the occurrence of various organic syndromes the char

parabasal body to form what are known as posteriorly nucleated forms The course of the disease is similar to that of the Gambian type, except that *Trypanosoma rhodesiense* is much more virulent for man and is much more resistant to treatment *Trypanosoma rhodesiense* is transmitted by *Glossina morsitans* and may be a human strain of the well known *T brucei* of animals In the insect its development is similar to that of *Trypanosoma gambiense* in *Glossina palpalis*, with the exception that it may be completed within fourteen days after ingestion of the infected material

Diagnosis—Although certain clinical symptoms arouse suspicion, definite diagnosis can be made only by demonstration of the parasite This is often difficult because of the scarcity of the parasites in the blood No reliable serologic tests have been devised and cultivation *in vitro* is too difficult to be of any service

Microscopic examination of the blood may be made either with a drop of fresh blood under a cover slip or with a stained smear The former method is preferable because the characteristic agitation of the blood cells by the living trypanosomes facilitates their detection If auto agglutination of the red cells is observed further search is always advisable In suspected cases when none of the organisms can be discovered it is best to examine a large quantity of blood Ten cc may be withdrawn from a vein citrated or oxalated and centrifuged at a low speed to throw down the red cells The supernatant fluid may then be withdrawn, recentrifuged at high speed, and the sediment examined for parasites Often by this method the trypanosomes may be discovered even though they are extremely scarce in the blood Thick films such as are used in the diagnosis of malaria are employed by some workers

Gland Puncture—When the glands (particularly those of the posterior triangle of the neck) are enlarged and soft their tissue fluid almost invariably contains trypanosomes A small quantity of this may be sucked out with a sterile dry hypodermic needle In old or treated cases where the glands are often sclerosed this method of course is unsuccessful

Lumbar puncture is of value in the second stage of nervous involvement because the sediment from centrifuged spinal fluid often contains trypanosomes Since the cell content of the spinal fluid increases with cerebrospinal involvement, the cell count may furnish a rough index of the extent of cerebrospinal invasion

Inoculation into Susceptible Animals—Laboratory animals such as rats mice guinea pigs rabbits and monkeys (*Macacus* and *Cercopithecus*) may be inoculated subcutaneously or intraperitoneally with suspected blood gland fluid, or spinal fluid, and their blood examined for trypanosomes

Trypanosoma gambiense and *T rhodesiense* can be differentiated by the posteriorly nucleated forms which develop in subinoculations of the Rhodesian strain into the smaller laboratory animals In lieu of this the characteristics of geographic distribution, virulence and resistance to chemotherapeutic agents are of value

Treatment of the diseases has greatly advanced since 1920 when tryparsamide and Bayer 205 were introduced into clinical use While the number of metallic and organic drugs which have been studied is large the number of compounds actually employed in therapy is small (see Findlay 1939, for a detailed account of these trypanocides) The more important in clinical use are (1) tryparsamide and (2) orsanine or Fourneau 270 among the pentavalent arsenicals, (3) neocryl a trivalent arsenical and (4) germanin or Bayer 205, or the French equivalent moranyl or Fourneau 309 Of the older drugs atoxyl tartar emetic, and antimony trioxide are still used either singly or to reinforce treatment with the drugs now in general use Their efficacy is practically limited to the earlier stages of the Gambian disease and with these three drugs prognosis of the Rhodesian disease in all stages and the Gambian infection in the latter stages is practically hopeless

The efficacy of tryparsamide in the treatment of trypanosomiasis probably lies to a large extent in the ease with which it penetrates the central nervous system In first stage cases according to Chesterman six, to eight weekly injections should be given The dose per kilo of body weight in children should be 0 07 Gm for young adults 0 055 Gm and for adults 0 045 Gm Second courses

Russian Turkestan and South America A few cases have been reported in the United States but all had contracted the disease in parts of the world where kala azar is endemic In India in the province of Bihar over 90 000 received treatment in one year

The disease is far more common in the country or villages than in cities In India and China the heavily infected areas are in the low lying alluvial plains In China the most heavily infected villages are in Kiangsu along the old bed of the Yellow River In some villages the disease assumes epidemic proportions Three hospitals in this area treat altogether over 5000 kala azar patients a year

There is no difference in sex incidence The greatest number of cases occur between the ages of five and fifteen After this the incidence falls as the age advances It is rare in individuals over sixty years of age

Etiology —The fact that in cultures and in some insects *Leishmania donovani* grows into a flagellate resembling the common insect herpetomonads suggests that an insect is an essential host In the sand fly (*Phlebotomus argentipes*) there is a remarkable development into flagellates which are virulent and which may escape from the proboscis during feeding Most investigators believe that the sand fly is the transmitting agent Thousands of attempts however have been made to transmit the disease to hamsters by means of the sand fly and in nine they have been successful For many years along the Mediterranean coast dogs have been under suspicion as the reservoir host of human kala azar Both in Malta and Peiping a few naturally infected sand flies have been found in association with infected dogs *L canis* and *L donovani* appear to be identical and the evidence at present available supports the view that in North China the dog is the reservoir of the disease It has been possible to transmit the infection by the oral route Leishmania has been demonstrated in the stools urine prostatic fluid and gastric contents and in the nasal and oral secretions of kala azar patients

Protozoology —There are two phases of the parasite the so-called "Leishman Donovan body" of the mammalian host, and the flagellate phase The Leishman Donovan body which is round or oval or piriform in shape contains two very characteristic structures by which identification of this body" in smears is made These are the nucleus and kinetoplast The nucleus which is almost spherical is about one third the diameter of the organism and often lies pressed against the membrane The kinetoplast is usually seen as a rod lying with its long axis directed toward the nucleus

In Romanowsky stained films the nucleus appears as a mass of red granules while the kinetoplast, which is a more solid compact body takes a deep reddish-purple tint When spherical, the diameter of the parasite is from 1 to 3 microns—when ovoid the long diameter is from 2 to 5 microns and the shorter from 1.5 to 2.5 microns

The flagellate form is a fusiform body observed in culture and in certain insects particularly in the sand-fly The general morphology of the flagellate stage is that of a typical Herpetomonas *i.e.*, it is an organism possessed of a single flagellum which rises in connection with a kinetoplast situated anteriorly to the trophonucleus and having no trace of an undulating membrane The usual length of the body of the parasite varies from 9 to 16 microns The breadth is usually about 1.5 microns The length of the flagellum is frequently about the same length as the body Rogers (1904) was the first to cultivate the organism and thus discover its flagellate phase It is most easily cultivated on the Novy McNeal Nicolle (N N N) medium at 22 C

Animal Inoculation —Hamsters (*Cricetus griseus*) white mice squirrels and dogs can be experimentally infected with this organism Some of these species tend to recover spontaneously from the infection Rabbits and guinea pigs are resistant.

Morbid Anatomy —Kala azar is essentially an invasion of the reticulo-endothelial system of the body by *Leishmania donovani* The parasites are taken up by the reticulo endothelial cells where they develop until the cell becomes distended and bursts discharging numerous parasites into the blood stream Here they are taken up by the mononuclears or clasmatocytes and also by the leukocytes The tissues react to the infection by a proliferation of the reticulo endothelial system There is also an increase in plasma cells in the spleen and bone marrow The increase in the cells of the reticulo endothelial system is so great as to cause a rapid increase in the size of the spleen The endothelial and Kupffer cells of the liver are also parasitized resulting in an enlargement of this organ The parasite is to be found in largest numbers where there is reticulo endothelial tissue that is in the spleen liver bone marrow and lymph nodes and in the endothelial lining of the small blood vessels throughout the body

In the most advanced infections the parenchymatous cells of the liver and adrenal cortex become parasitized and severe

acter of which depends upon the systems and organs chiefly involved Considerable doubt exists as to whether all of the symptoms described by Chagas are actually due to *Trypanosoma cruzi* or to superimposed conditions

Diagnosis—Diagnosis can only be made definitely by finding the parasites They are most easily found during the acute stage when the trypaniform organisms are still in the blood and when their presence can be demonstrated by microscopic examination or injection into susceptible laboratory animals Parasites can be occasionally found in small numbers during the chronic stage, but whether this is due to the chronic infection or to reinfection is not known In endemic regions the trypanosomes are sometimes accidentally discovered in thick blood films prepared for malarial surveys Gland puncture has not been of any value in this infection but when there is cerebrospinal involvement the parasites have sometimes been found after lumbar puncture Attempts to recover the leishmania stages by puncture of the various muscles and organs have not been successful Complement fixation tests (Machado reaction) have been devised and preliminary work indicates that they are of value Kelser has recently prepared an antigen of high potency from artificial cultures of the parasites

Treatment—The usual trypanocides are not effective and so far no satisfactory drug treatment has been devised A number of patients apparently recover spontaneously

LEISHMANIASIS

THREE diseases kala azar cutaneous leishmaniasis and American leishmaniasis may be considered under the heading *Leishmaniasis* as the parasite in each case is morphologically identical The three diseases, however differ clinically and have in general a different geographic distribution

E B STRUTHERS

KALA AZAR

(*Visceral Leishmaniasis Dumdum Fever Black Fever*)

Definition—Kala azar is an infectious disease characterized by enlargement of the spleen and usually of the liver long continued irregular fever, anemia and leukopenia with progressive loss of weight and strength It is caused by a protozoon *Leishmania donovani* which is present in the spleen, liver peripheral blood and the cells of the reticulo endothelial system

History—The disease is known to have existed in India since 1869 it was however not accurately described until Clark in 1882 reported an epidemic that had been raging in Assam for some years He states that there is a fever of malarial poisoning known among the natives as kala azar or black sickness from the darkened colour which the skin assumes in chronic cases Sporadic cases with similar symptoms were also observed in Italy and the Greek islands The disease was not definitely differentiated from malaria and other fevers until Leishman in 1903 described the parasite found in the spleen of a soldier who had died of a long continued fever contracted at Dumdum in Bengal The same year Donovan in Madras independently found the parasite in spleens postmortem and in a living patient by splenic puncture Laveran and Mesnil named the organism *Leishmania donovani*

Incidence—The most heavily infected areas are in Eastern India and in North China It has been found in all the countries which border on the Mediterranean the Sudan West Africa Iraq Southern Russia

neostam and urea stibamine the initial dose should be 0 05 Gm and the maximum dose 0.2 Gm or 0 25 Gm continued until a total of 2 6 or 2 8 Gm has been given In children the initial dose of neostibosan is 0 05 Gm and the maximum dose 0 2 Gm Very small children should be given doses proportionate to their weight Fewer reactions occur in children than in adults These drugs may produce such toxic effects as fever cough nausea vomiting lymphadenitis and headache After evidence of toxic action the amount given at the next injection should be reduced or the interval between the injections lengthened If the toxic symptoms are serious it is advisable to substitute one of the other pentavalent compounds

A new antimony compound solustibosan is less toxic than neostibosan It has the advantage of forming a stable solution and may if necessary be injected intramuscularly A number of patients have been successfully treated with 4 4 diamidino stilbene Symptoms of shock after the injections are not uncommon but no deaths have been reported

With the pentavalent antimony compounds a recovery rate of 90 per cent is to be expected About 3 per cent die during treatment and 6 per cent relapse The relapse rate bears a relation to the total amount of the drug injected

A diet adequate in protein and vitamins is advisable Liver and some form of iron should also be prescribed

In a patient who progresses favorably during treatment the temperature returns to normal there is an increase in weight and strength and a decrease in the size of the spleen and there is also an increase in hemoglobin erythrocytes and leukocytes An increase in leukocytes is a good prognostic sign but there is no way to foretell at the end of a course of treatment whether a patient will or will not continue to improve until all the parasites are exterminated The only satisfactory method is to reexamine the patient at the end of one three and six months The only proof of cure is freedom from symptoms and signs of the disease for at least six months

Post kala azar dermal leishmaniasis which was first described by Brahmachari in 1922 is a sequela of generalized leishmania infection The dermal lesions make their appearance from one to two years after treatment after all signs of the visceral infection have disappeared The skin eruption appears as depigmented areas erythema or butterfly rash and nodules More rarely it is of the verrucose papillomatous or xanthoma type *Leishmania donovani* may be found in the skin lesions but not by spleen puncture

E B STRUTHERS

CUTANEOUS LEISHMANIASIS

(Oriental Sore Aleppo Boil Delhi Boil)

Definition —Cutaneous leishmaniasis is an ulcerating granuloma of the skin caused by the protozoal parasite *Leishmania tropica*

History —The same month that Donovan described the etiologic agent of kala-azar an Armenian was admitted to the Massachusetts General Hospital in Boston presenting what was diagnosed as tropical ulcer In the excised tissue, Wright found the parasite now called *Leishmania tropica*

Incidence —The disease is widely distributed The names mentioned above suggest parts of the world where the disease is common It is found in India Persia Palestine Africa and countries around the Mediterranean Sea in Costa Rica Brazil and Peru

Etiology —The *Leishmania tropica* cannot be distinguished microscopically from *L donovani* of kala azar already described Dogs in Persia and Algeria have been found naturally infected There is little doubt that the usual vector is the sand fly (*Phlebotomus*) though it is possible that houseflies may carry *L tropica* and so infect open wounds It may be directly inoculated from man to man

Symptoms —The incubation period varies from a few weeks to several months The lesion may appear on any exposed part of the body usually on the upper extremity or on the face It begins as a small red papule (single or multiple) which gradually enlarges becomes purplish in color and soft in the center The surface breaks down and an ulcer with round edges is formed The sores are usually about 1 inch in diameter In the nonulcerating variety fluid obtained by puncture will yield many parasites To find parasites in ulcerated sores it is well to

areas, schistosomiasis is not found this test has been found of great value in ruling out febrile conditions with splenomegaly due to malaria and other diseases In this test 0 02 cc of blood is collected in a Sahli hemoglobin pipet and emptied immediately into a small test tube containing 0 6 cc of freshly distilled water The contents of the tube are quickly mixed and the tube allowed to stand without further shaking At the end of five minutes, a haziness or cloudiness should be present in all positive tests and the tests that show a definite settling or fairly complete sedimentation of the precipitate within fifteen minutes are considered strongly positive those in which this change does not occur until after fifteen to thirty minutes moderately positive those between thirty and sixty minutes weakly positive and those that show only a haziness and a very fine precipitate but no sediment even after one hour very weakly positive Only strongly positive tests are of value as other diseases may give weakly positive results Leukemic blood, owing to numerous undissolved nuclei of the leukocytes will give a false positive A drop of acetic acid will dissolve the globulin but not the cell nuclei

The Formalin Test (Aldehyde Test) — One drop of 30 per cent formalin is added to 1 cc of clear serum in a small test tube and immediately mixed by shaking Serum from well established cases of kala azar (three or four months or more) will become solid and opaque like the 'white of a hard boiled egg in less than half an hour If the opacity is only partial (opalescent) the result is doubtful and if no change occurs within twenty four hours the result is considered negative Gel formation an associated factor is not by itself of any value in the diagnosis of kala azar

Antimony Test —On adding 2 drops of the patient s serum to 1 cc of 0 5 per cent solution of urea stibamine or other pentavalent antimony compound a heavy precipitate is formed

These tests are positive in about 90 per cent of kala azar sera in which they demonstrate a marked increase of euglobulin When negative in a patient with an enlarged spleen they are of definite value in excluding kala azar

Differential Diagnosis —Kala azar must be differentiated from the following diseases malaria typhoid fever schistosomiasis syphilitic splenomegaly tuberculosis undulant fever and bacterial endocarditis The water formalin and antimony tests are often positive in bacterial endocarditis In any obscure fever, associated with splenic enlargement and progressive leukopenia, the possibility of kala azar should be considered

Prognosis —Without treatment it is probable that over 90 per cent of kala azar patients die within two or three years By the introduction of antimony in treatment, especially the pentavalent antimony compounds the rate of recovery is now as high as the former death rate Occasionally those who without treatment survive cancrum oris or pneumonia are found to have also recovered from the primary disease

Treatment —Antimony discovered in 1908 to be lethal to trypanosomes was found by Di Cristina and Caronia in 1914 to cure cases of kala azar in children They injected a solution of tartar emetic intravenously Its value in kala azar was soon confirmed by Rogers, Muir and others in India Previous to the introduction of antimony many drugs had been tried without success Since that time thousands of patients have been cured with tartar emetic or sodium antimony tartrate The course of treatment however with these drugs was long and tedious extending over a period of three or four months Reactions were not infrequent and about 10 per cent of the cases treated died from toxic reactions or complications caused by the antimony

For these reasons one of the newer pentavalent antimony compounds should always be used Their toxicity is almost one twentieth that of tartar emetic reactions are fewer a cure can be effected in three weeks and the recovery rate is considerably higher The compounds which have been most used are neostibosan urea stibamine and neostam All are given by intravenous injection The drug is dissolved in freshly distilled water to make a 5 per cent solution Neostibosan may be given in daily injections but is usually given on alternate days in the following doses 0 1 Gm 0 2 Gm 0 25 Gm or 0 3 Gm If no reactions occur the maximum dose is continued until for a patient weighing 100 pounds 3 Gm has been given With

not only asexual propagation but maturation and fertilization of the sex cells are carried out with a brief extrinsic phase for the production and ripening of the sporozoites

The Sarcosporidia and species of *Toxoplasma* have previously been placed by some investigators in the Class Sporozoa although there appears to be little or no justification for this view These organisms should rather be grouped in a category of *Sedes Incertae* but for convenience will be considered briefly as an Addendum to this Class group

The malaria parasites and human malaria are presented elsewhere in this volume (p 374)

ERNEST CARROLL FAUST

COCCIDIOSIS

(*Coccidiasis*)

Coccidiosis is an infection caused by sporozoan parasites belonging to the genera *Isospora* and *Eimeria* While several species of these organisms have been reported from man all except one (*Isospora hominis*) have on careful scrutiny been found to be spurious parasites taken into the human digestive tract in infected fish

Isospora hominis has been inadequately studied due for the most part to its relatively uncommon occurrence in areas where modern medical examination is available in part to the moderate symptoms usually associated with its presence and finally to the fact that no postmortem data are available The writer has had the opportunity of observing five clinical cases on which this presentation will be primarily based

History —According to Virchow (1860) *Isospora hominis* was probably discovered by Kjellberg earlier in that year in the villi of the human ileum This was confirmed by Eimer in 1870 The 208 human infections reported have been from the Mediterranean countries from several foci in East, West, South and Central Africa, China, Indo-China, the Philippines Dutch East Indies India, South America Hawaii and the United States

Morbid Anatomy —The schizogonic phase of the life cycle in man is undescribed but is believed to occur in the villi of the lower portion of the ileum where the encysted fertilized eggs (*oocysts*) are formed pass down the bowel and out in feces They are slightly irregular elongate ovoidal objects measuring 20–33 by 10–19 microns and contain a single spherical cell In fecal samples at warm room temperatures the single cell soon divides into two smaller spheres (*sporoblasts*) within each of which there are formed four crescentic *sporozoites* The *sporocyst* with its eight sporozoites is now infective for man and if taken into the mouth in feces-contaminated food or drink will presumably hatch in the small bowel and initiate a new infection

Clinical History.—The infected patients seen by the writer in China gave a common history each sought relief from a severe watery mucous diarrhea of several days standing They were put to bed placed on a bland diet and in the course of ten to fifteen days had completely recovered Follow up examination from one to three months later confirmed this finding Parallel with the clinical observations the oöcysts were very plentiful in the stools of the patients on admission to the hospital diminished gradually and before the patients discharge had completely disappeared There is thus some evidence indicating that rest and diet contributed to a spontaneous evacuation of the organisms from the human body Although many species of *Isospora* have been described from domestic and wild animals none is morphologically similar to *I hominis* Thus the relatively few sporadic cases of human infection remain epidemiologically unexplained (Magath 1935)

Prevention presumably consists in care not to take food or drink contaminated with *I hominis* spores

ERNEST CARROLL FAUST

SARCOSPORIDIOSIS

This infection is produced by the organisms belonging to the genus *Sarcocystis* a member of the group SARCOSPORIDIA the systematic position of which is undetermined It is even probable that these parasites are not protozoan forms at all and may possibly be fungi like pecies of *Rhinosporidium* which were previously classed as protozoa *Sarcocystis* de cribed under several species names is a fairly widespread infection in reptiles birds and mammals including sheep cattle horses and rodents

Morbid Anatomy —One species *Sarcocystis lindemanni* Rivolta 1878 has been

obtain fluid from the tissues below the contaminated surface After a variable period of three months to a year healing begins A slightly depressed disfiguring scar remains One attack confers immunity

Treatment—When possible excision with the electrocautery is often the method of choice Good results are claimed by applying sulfapyridine or Uleron directly in powder form to the sore after cleansing with saline solution A 2 per cent ointment of antimony tartrate of fuchsin paint may be applied locally Berberine sulfate 3 or 4 cc of a 1 per cent solution may be injected into the tissues about the ulcer Two to 5 injections often effect a cure Carbon dioxide snow, x rays and ionization are all said to be useful In the epidemic at Quetta sores were scraped under gas anesthesia followed by the application of pure carbolic acid and a cover of elastoplast The cover was left in position for two weeks

E B STRUTHERS

AMERICAN LEISHMANIASIS

(Mucocutaneous Leishmaniasis Nasopharyngeal Leishmaniasis Espundia Brazilian Leishmaniasis)

Definition—American leishmaniasis is a type of cutaneous leishmaniasis which differs clinically from oriental sore in that it affects the mucous membranes of the nose and throat in from 10 to 20 per cent of the cases

Incidence—With the possible exception of Chile the disease occurs in every country of South America It is especially prevalent in Brazil Peru and Bolivia In Paraguay it is said to have assumed epidemic proportions

Etiology—As in oriental sore scrapings from the lesion show the presence of a parasite similar to *Leishmania donovani* or *L tropica* which has been called *L braziliensis* The sand fly again is the probable transmitter

Symptoms—The sore may appear on any exposed part of the body and presents the appearance of oriental sore or it may begin on some mucous surface where it produces a fungating ulcer The sores infiltrate the deeper tissues causing destruction of the nose and parts of the face The pharynx and larynx may be affected

Treatment—The treatment is the same as that for oriental sore Sodium arsenite 0 005 Gm three times a week or 0 01 Gm twice a week intradermally has been recommended

SPOROZOAN INFECTIONS

SPOROZOAN infections are produced by the one celled (or a cellular) animals belonging to the Class SPOROZOA All members of this Class are parasitic Some are in invertebrate hosts probably many more in vertebrates and a few very important ones produce disease in man All of these parasites require an alternation of asexual reproduction (*schizogony*) and sexual reproduction (*sporogony*) to complete a life cycle The two important groups of Sporozoa which parasitize man are the Hemosporidia and the Coccidia In the Hemosporidia all or part of the asexual stage occurs in the blood cells of the intermediate host while maturation of the sex cells fertilization and sporozoite production take place in the definitive host The most notable examples of the Hemosporidia parasitizing man are the malaria parasites of which man is the intermediate host and the *Anopheles* mosquito is the definitive host In the Coccidia only a single host is required in this host

CILIATE INFECTIONS

BALANTIDIASIS

(*Balantidiosis*)

THE CILIATA constitute a distinct class group of the PROTOZOA They are unicellular organisms which have numerous meridional rows of relatively short threadlike extensions of their cytoplasm the *cilia* anchored in basal granules within the limiting membrane or *pellicle* These cilia are organelles of locomotion and those near the anterior end also frequently serve to bring food into the *cytostome* or primitive mouth which lies to one side of the anterior extremity Ciliates have a large sausage-shaped *macronucleus* and at least one *micronucleus* and multiply by transverse binary fission Most species characteristically undergo conjugation a reciprocal exchange of nuclear material Some species encyst when environmental conditions are unfavorable to growth and propagation The great majority of ciliates are free living forms but a few are obligatory parasites Of these latter only one *Balantidium coli* is medically important

History.—*Balantidium coli* (Malmsten 1857) was first seen by Malmsten in 1857 in the stools of two Swedish patients who were suffering from dysentery Since its discovery this parasite has been reported as having an extensive distribution in Northern Southern and Eastern Europe the U S S R, including Siberia China, Ceylon Java and the Philippines Egypt, the Sudan and Abyssinia several of the countries of South America, Honduras Cuba and Puerto Rico and in several of the United States While most species of monkeys harbor a natural infection of *B coli* human balantidiasis is almost invariably linked to association with pigs which are the important reservoir

Life Cycle—*Balantidium coli* is the largest of the protozoan parasites of man ranging in length from 50 to 100 microns and in breadth from 40 to 70 microns The living organism is a sturdy ovoidal glassy green object which is covered with many rows of cilia arranged in a slightly oblique pattern from upper left to lower right (as seen under the compound microscope) A *cystostome* or cell mouth for the intake of food is readily observed somewhat to one side of the anterior extremity At the aboral end is a primitive anus Within the body is a large slightly curved *macronucleus* and near the center of its concave margin a minute *micronucleus* Numerous food and contractile vacuoles constitute the other conspicuous organelles of the parasite By means of its multitude of cilia beating synchronously *B coli* moves ahead in a slightly spiral path It avidly ingests particulate food stuffs including starch grains It divides by transverse binary fission In a film of semi formed or liquid stool the motile *Balantidium* may be observed under the microscope to plough through the medium then become relatively quiescent round up partially retract its cilia and secrete a tough cyst wall around itself It does not multiply during the cystic stage

Morbid Anatomy.—As a parasite of man *Balantidium coli* invades the wall of the large bowel especially in the region of the cecum Its entry into the tissues is primarily mechanical although it probably possesses some lytic properties In uncomplicated infections the lesion produced is cup like or flask like but due to its relatively larger size the opening is larger than that produced by *Endamoeba histolytica* At times there may be deep pockets or burrows considerably below the muscularis mucosae and rarely the organisms gain entry to mesenteric blood vessels However there is apparently no record of *Balantidium* setting up foci of infection in the liver In uncomplicated lesions there is no evidence of local or generalized host cellular reaction to the invader except attempts of fibroblastic repair In chronic balantidiasis the lesion is frequently complicated by bacterial invaders which call forth a concentration of neutrophilic leukocytes and small monocytes in the immediate vicinity

Clinical History—The usual patient harboring *B coli* gives a history of association with pigs from which reservoir the infection has undoubtedly been contracted as a result of the ingestion of cysts of the organisms taken into the mouth on contaminated fingers food or drink soiled with pig s dung These patients either have an inapparent infection (*i e* are carriers) or have a moderate to severe water mucous diarrhea usually without macroscopic blood Constipation may alternate with diarrhea The writer has seen these two types on several occasions in China Panama Puerto Rico and in the Charity Hospital in New Orleans and knows of other infections in Arkansas

reported on nine occasions from man It parasitizes the striated muscles and connective tissue rarely the unstriated muscles of its host, developing in elongated spindle shaped membranous capsules having rounded ends and internal septa Within the capsules are myriads of sickle shaped spores or *sarcocysts* which are most plentifully developed in muscles of the throat chest diaphragm and abdomen The mother capsules measure up to 25 mm in length the spores 12–16 by 4–9 microns The exact manner in which man becomes infected is unknown but it is believed that the ripe spores are accidentally swallowed in food or drink and by means of a digestive ferment (*sarcocystin*) gain entry to the musculature *via* the intestinal wall

Diagnosis can be made by biopsy and at autopsy by demonstration of the capsules with their spores This infection should not be confused with trichinosis (p 411) which also parasitizes striated muscles In extensive involvement of the musculature some degeneration may occur and a mild cachectic state may develop There is no specific *treatment*

Prevention consists in care not to ingest uncooked meat or possibly raw water in which infected dead reservoir hosts may have disintegrated

ERNEST CARROLL FAUST

TOXOPLASMOSIS

Until very recently this clinical entity was poorly understood and poorly defined The infection is produced by species of the genus *Toxoplasma* organisms which have been recovered from body fluids and exudates but typically reside intracellularly in mononuclear and epithelioid cells nerve cells muscle fibers endothelial cells of capillaries and polymorphonuclear and eosinophilic leukocytes Dozens of species of *Toxoplasma* have been described based primarily on the vertebrate hosts they parasitize but there is practically no proof that they represent other than strains of the same species They are minute (2–6 by 1.5–2 microns) distinct oval pyriform rounded crescentic or elongated protoplasmic masses each with a more or less central nucleus They occur singly or in clusters in the host cell and multiply by repeated binary fission

History.—The three earlier records of human *Toxoplasma* infection (*T pyogenes*) reported by Castellani (1914) Federovitch (1916) and Chalmers and Kamar (1920) are today not subject to verification. The more recent reports (Janku 1923 Torres 1927 Hertig, 1936; Wolf and Cowen 1937 Richter 1938 Wolf Cowen and Paige 1939 Pinkerton and Weinman 1940 Sabin, 1939 1941 and Pinkerton and Henderson, 1941) involve infants children and adults suffering from fatal or severe encephalomyelitis and adults with a syndrome simulating fatal rickettsia disease In at least two of these cases guinea pigs became positive after inoculation with material from the living patient or at necropsy and developed characteristic lesions

It is possible that inapparent toxoplasmosis may be relatively common in human beings and in various animals which then may serve as carriers although the method of transmission is unknown In clinical cases the *prognosis* is almost invariably grave There is no *specific treatment* although sulfathiazole and sulfapyridine have been demonstrated by Sabin and Warren (1941) to have a curative effect on toxoplasmosis in mice Protection tests in laboratory animals suggest the possible development of protective vaccines

Among the flatworms there are two classes containing important human parasites These are the TREMATODA or flukes and the CESTOIDEA or tapeworms

ERNEST CARROLL FAUST

TREMATODE OR FLUKE INFECTIONS (*Trematodiasis*)

Trematodiasis is an infection with species of TREMATODA (Flukes), which possess the general characteristics of the PLATYHELMINTHES but with the following restrictions the ciliated epithelium is confined to the larva (*miracidium*) hatched from the egg typically flukes have a mouth surrounded by a muscular sucker a pharynx esophagus and a pair of intestinal ceca which end blindly in the subdistal portion of the body All flukes parasitizing man have a complicated life cycle involving a minimum of three generations and obligatory utilization of certain species of snails (or other molluscs) as intermediate hosts The larval stage hatched from the egg (*miracidium*) actively invades the appropriate snail in which a two fold multiplication occurs The tailed larva emerging from the snail (*cercaria*) becomes a free living aquatic form and has one of three recourses depending on the species of fluke It may directly infect man by the skin route (blood flukes) it may crawl onto aquatic vegetation drop its tail and excyst on the surface of the plant (sheep liver fluke) it may penetrate into the soft tissues of certain animals where it encysts (Chinese liver fluke) In the latter two groups man acquires the infection by ingesting raw or inadequately cooked plant or animal food infected with the respective cysts

Most flukes infecting man are hermaphroditic and possess two distinct suckers one surrounding the mouth and a blind acetabulum on the ventral side of the body These species are referred to as *distomes* and their infection is properly designated as *distomiasis* Important exceptions are the blood flukes or *schistosomes* which are unisexual (*i e* diecious) Infection with these latter species is designated as *schistosomiasis*

ERNEST CARROLL FAUST

INTESTINAL DISTOMIASIS

Several species of flukes parasitize the digestive tract of man in most instances the small bowel where the worms are attached to the mucosa by means of their suckers

Fasciolopsis buski —The large fleshy fluke *Fasciolopsis buski* is an important parasite of man (and the pig) in the neighborhood of the China Sea the Southern Pacific Ocean Burma and Eastern India It lives primarily in the levels of the duodenum and jejunum These flukes measure 20 to 75 mm long 8 to 20 mm broad and 0.5 to 3 mm in thickness They lay large colorless transparent thin shelled ovoidal eggs (measuring 130–140 by 80–85 microns) which have a minute operculum They mature only after they have been evacuated in feces into fresh water After several days a miracidium hatches from each egg seeks out and penetrates into its appropriate snail host and undergoes a two fold multiplication within the snail The cercariae which are shed from the snail a few weeks later crawl onto and encyst upon the seed pods of the water caltrop bulbs of the water chestnut roots of the lotus water bamboo or other aquatic plants Man becomes infected when he peels off the hull or skin of these plant products between his teeth and lips before swallowing the raw foodstuff

Symptoms —Wherever the adult worm is attached to the intestinal mucosa there is first a focus of inflammation later a necrotic center with hemorrhage and frequently abscess formation Many worms attached near together at one level of the bowel may produce an acute obstruction Towards the end of the incubation period of about 90 days there is a toxic diarrhea with hunger pains Heavy infections may simulate peptic ulcer and the patient may become asthenic Generalized toxemia is usually manifested in the form of edema particularly of the face abdominal wall and lower extremities Ascites develops in severe infections especially in children Generalized abdominal pain is frequent The diarrhea continues the stool becomes foul smelling and contains much undigested food Anorexia nausea and vomiting are characteristic Death is commonly due to anasarca Most of the patients have a marked leukocytosis with absolute eosinophilia but some

and Kentucky At least one endemic focus of human balantidiasis has been reported from a mental hospital in the United States, *suggesting that the infection is more widespread in this country than has been as sumed* Occasionally severe *balantidial dysentery* with the copious discharge of blood has been reported Even if there is only shallow invasion of the colon and no characteristic postmortem evidence of invasion the bowel mucosa may be hyperemic with superficial necrosis and hemorrhage

In most patients balantidial diarrhea or dysentery is accompanied by abdominal colic tenesmus nausea and vomiting loss of appetite, headache insomnia muscular weakness and loss of weight due to dehydration and poor digestion and absorption of food There is at times a pallor of the skin and mucous membranes and a moderate secondary anemia Usually physical examination will exhibit a tenderness over the colon At times there is an exhausting watery diarrhea or dysentery

Diagnosis of balantidiasis is made by the demonstration of the characteristic trophozoites or cysts of the parasite in the patient s stool These are readily seen under the compound microscope in unconcentrated fecal films and the essential features are well distinguished in fresh films stained with D Antoni s iodine Inexperienced diagnosticians must not mistake for *Balantidium coli* the free living ciliates which grow in old dropping bottles of distilled water or physiologic salt solution and thus may contaminate the fecal films during its preparation *Prognosis* without treatment may be good to poor Some infections probably clear up spontaneously others become chronic and gradually sap the strength of the patient rarely the infection may fulminate and cause death

Treatment of balantidiasis is not particularly satisfactory due perhaps to the fact that in recent years recognized cases have been relatively few and therapy has been mostly sporadic Carbarsone as administered in amebiasis one 0 25 Gm (4 grain) capsule twice daily with meals for ten days, has been helpful in a few instances Chiniofon and vioform should be given adequate trial In case bacillary dysentery complicates balantidiasis sulfonamides should be used as an adjuvant

Prevention consists in meticulous care not to contaminate food or drink with pig's dung and to wash the hands thoroughly before putting them in the mouth

METAZOAN INFECTIONS

THE METAZOA are animals made up of many cells which in aggregates are usually specialized into tissues and organs performing particular but coordinated functions of the entire organism In this respect the METAZOA differ from the PROTOZOA the one-celled (or a cellular) organisms in which all of the functions are performed by specialized portions of the protoplasm within a single cell unit The parasitic Metazoa are found primarily within the following invertebrate groups the PLATYHELMINTHES or flatworms the NEMATHELMINTHES or roundworms the HIRUDINEA or leeches and the ARTHROPODA comprising the insects and their allies

THE PLATYHELMINTHES

(*Flatworms*)

MEMBERS of this group are invertebrates which have primitively a ciliated epithelium covering the body They have a longitudinal axis with anterior and posterior ends and are bilaterally symmetrical With few exceptions they have either an incomplete digestive tract or none at all There is no body cavity what otherwise would be a body cavity is filled with loose mostly undifferentiated parenchyma cells in the midst of which are located the excretory organs nerve ganglia and trunks and particularly the greatly elaborated genitalia Most of the flatworms are hermaphroditic and thus each individual is a complete reproductive unit

TREATMENT should be instituted if possible before the worms burrow into the intestinal mucosa Caprokol as recommended in *Fasciolopsis buski* infection may be instituted but tetrachlorethylene (C_2Cl_4) is believed to be more specific The adult dosage is 3 cc (45 minims) given in the morning on an empty stomach preceded the night before and followed 2 hours after treatment by Glauber salts purgation (1 ounce or 30 cc dissolved in a glass of water) No food should be permitted until a copious post treatment bowel movement has been obtained Tetrachlorethylene is safe in the absence of alcohol and absorbable fats and should remove all heterophyid worms except those which are deeply imbedded in the bowel wall

PREVENTION consists in the thorough cooking of all fish in endemic areas

Amphistomes —Two other large intestinal flukes referred to as amphistomes because their suckers are at opposite ends of their body have been reported from man *Watsonius watsoni* in West Africa and *Gastrodiscoides hominis* in India Cochin China and among East Indian immigrants in British Guiana Practically nothing is known of their life cycles or epidemiology They produce severe diarrhea indigestion and generalized toxemia with anasarca Caprokol as recommended for *F buski* is likely to prove efficacious for their removal

ERNEST CARROLL FAUST

HEPATIC DISTOMIASIS

Hepatic distomiasis is produced by the sheep liver fluke (*Fasciola hepatica*) and its relatives the Chinese liver fluke (*Clonorchis sinensis*) and its relatives (*Opisthorchis felineus* and *O viverrini*) and by the lancet fluke (*Dicrocoelium dentriticum*)

Fasciola hepatica and its kin *F gigantica* are the largest hepatic flukes measuring about 30 by 13 mm

Life History —As adults they live in the more proximal bile ducts and gallbladder where they lay large colorless transparent, thin shelled unembryonated ovoidal eggs (measuring 130–160 by 63–90 microns) with a minute operculum These eggs hardly distinguishable from those of *Fasciolopsis buski* pass down into the lumen of the bowel and are evacuated in feces They mature in fresh water and undergo an extrinsic life history paralleling that of *F buski* Herbivorous animals grazing on infected swampy pastures are commonly exposed to infection. After the cysts are swallowed with grass and excyst in the duodenum the larvae bore through the intestinal wall into the peritoneal cavity then bore through Glisson s capsule into the liver burrowing through the parenchyma and liver cells until they reach the larger bile ducts Here they grow into adults Sheep liver fluke infection is cosmopolitan wherever sheep are raised Human infections have been reported from Cuba Puerto Rico Mexico Central and South America Southern and Southeastern Europe Africa the U S S R the Near East and the Far East The commonest source of human fascioliasis in Europe and the Western Hemisphere is water cress

Morbid Anatomy —Heavy invasion of the liver by *F hepatica* results in extensive necrosis of the parenchyma (liver rot of sheep) After the worms reach the bile ducts they provoke a hyperplasia of the biliary epithelium with a circumscribing fibrous encapsulation resulting in pressure necrosis of the parenchyma and eventual periportal cirrhosis Symptoms and signs in human infections consist of hepatic colic generalized abdominal rigidity and pain on pressure irregular fever more or less persistent diarrhea leukocytosis with eosinophilia marked anemia anasarca and rarely hemoglobinuria

Diagnosis consists in recovering the characteristic eggs in the feces of persons outside Fasciolopsis endemic areas or from biliary drainage False distomiasis resulting from the consumption of infected sheep or cattle liver must be ruled out *Prognosis* is fair to poor depending on the degree of involvement *Treatment* as outlined by Kouri (1932) consists in the intramuscular administration of emetin hydrochloride (0 03 Gm or ½ grain daily for 17 to 18 days) and has been demonstrated to be quite effective in killing the worms

Prevention consists in meticulous care not to eat raw water cress or other water plants in endemic foci

Other Species —*Clonorchis sinensis Opisthorchis* spp and *Dicrocoelium dendriticum*

chronic cases have a relative lymphocytosis There is no significant anemia

Diagnosis is based on the history of the patient, his residence in endemic foci and the recovery of the characteristic eggs in the feces Prognosis is fair to good in properly treated cases

Treatment—The treatment of choice consists in the administration of caprokol (hexylresorcinol crystoids) in amounts of 0 4 Gm (6 grains) to 1 Gm (15 grains), depending on the age of the patient The drug is administered in 0 2 Gm (3 grains) *hard gelatin capsules* on an empty stomach and is followed in two hours with Glauber salts purgation (one ounce or 30 Gm dissolved in a glass of water) Food must not be taken until four hours after the anthelmintic has been administered In severe infections supportive treatment for the heart may be needed during and immediately following specific therapy Caprokol treatment has a 75 to 100 per cent worm removal value for *F buski* and may be repeated safely within one week

Prevention can be provided by immersing raw vegetables in boiling water for a few seconds The 'seedbeds of the infection may be eradicated by mass treatment of the infected population, together with destruction of the snails by the use of copper sulfate solution (1 to 50 000) in submerged fields where the infected water plants are grown

Other Intestinal Flukes—Several species of flukes small to large and fleshy in character are provided with an incomplete circlet of hooks on the cervical region of their body and are designated as echinostomes

Species belonging to the genera Echinostoma Himasthla Paryphostomum and *Echinochasmus* These have been reported as parasites of the human bowel particularly in the Far East (the Philippines Celebes Malaya India China and Japan) as well as in Roumania and elsewhere

Infection results from eating a variety of raw animal products including snails limpets tadpoles fresh water fish and so on in which the cercariae have encysted The smaller species produce only minor intestinal symptoms but the larger species cause grave symptoms comparable to *Fasciolopsis* infection

Treatment should be carried out along lines indicated for *F buski*

Prevention consists in the thorough cooking of all animal foods

Another type of intestinal distomiasis is produced by many flukes belonging to the family Heterophyidae and represented by the species *Heterophyes heterophyes Metagonimus yokogawai* and their kin which have an extensive distribution in the Far East Egypt, and Southeastern Europe These worms are minute forms at times barely visible to the naked eye are ovoidal, pyriform or nearly cylindrical and possess a peculiar union of their ventral and genital suckers They lay minute ovoidal eggs (measuring 26–30 by 15–17 microns) with a distinct operculum at one end The encysted cercariae are found in the tissues of many species of fresh water and some brackish water fishes

Morbid Anatomy—When various mammals (and frequently birds) eat the infected fish either raw or inadequately cooked these worms gain entrance to the small bowel excyst and attach themselves directly to the lining cells of the glandular crypts or become buried in the cells at times even reaching the stroma of the villi They produce an inflammation of the contiguous or invaded cells with excessive mucous secretion and erosion of cell membranes Worms which have entered the mucous membrane remain there until they die If the number of worms is large and the involved areas of mucosa are considerable a mucous diarrhea may result Until relatively recently these rather mild lesions were believed to constitute the entire story of host tissue involvement but Africa and his colleagues (1935 *et seq*) in the Philippines have demonstrated that in man the minute eggs not infrequently get into the mesenteric lymphatics or venules and are carried to many sites in the body including the myocardium brain spinal cord kidneys etc There they block the blood capillaries and stimulate foreign body reactions setting up trains of symptoms dependent on the organs and tissues involved Thus myocardial invasion may lead to a syndrome simulating wet beriberi or a progressive hypertensive myocarditis brain or spinal cord lesions loss of motor or sensory function at the levels of the lesions

implantations may abscess into the intestine or through the somatic tissues Glandular in volvement may be accompanied by fever Brain tumors the size of a hazelnut or larger may produce a Jacksonian type of epilepsy

Diagnosis is based on finding the characteristic eggs in sputum which is usually blood tinged Because of the macroscopic resemblance of the eggs to minute iron filings there is no serious likelihood of confusing the discharge of pulmonary distomiasis with that of pulmonary tuberculosis or bronchial spirochetosis

Prognosis is usually good unless the worms become lodged in foci like the brain There is no effective treatment Unless reinfected the average patient eventually overcomes the parasites and the lesions heal without dysfunctioning fibrosis

Prevention consists in care not to eat raw or pickled crab or crayfish meat

Ernest Carroll Faust

SCHISTOSOMIASIS

(Bilharziasis)

Schistosomiasis is produced by the schistosomes or blood flukes of which there are three important species of the genus *Schistosoma* parasitizing man over extensive areas of the globe These worms are delicate elongate organisms which live in the portal blood system and collateral venous circulation They are unisexual (*i e* diecious) although during insemination and oviposition the female is held in the long incurved ventral trough of the male (the *gynecophoral canal*) Pairs of the adult worms typically reside in the smaller venules of the bowel wall (*Schistosoma japonicum* and *S mansoni*) or of the vesical and pelvic plexuses (*S haematobium*)

Life History —At the time of oviposition the female extends her thread like anterior extremity as far up into the lessening diameter of the venule as she can then deposits an egg She then contracts a little and lays a second egg just behind the first and another and another until the entire venule is filled with the eggs The pair then back out enter another venule and repeat the process This continues until the entire venous radicle is packed with eggs At the time the eggs are laid or shortly thereafter the larvae (miracidia) within the eggs are fully embryonated and contain unicellular glands elaborating lytic ferments It has been demonstrated that minute droplets of these viscous fluids ooze out through submicroscopic pores in the eggshell into the venule in which the eggs are trapped The digestive action of this ferment, together with the pressure within the venule occasioned by the presence of the eggs weakens and soon ruptures the wall of the venule causing the discharge of the eggs into the perivascular tissues of the bowel or bladder wall Some of these eggs in the mucous or submucous membranes soon effect a passage to the lumen of the respective organ are carried down the bowel or urethra and are evacuated with feces or urine Hemorrhage from the wall of the organ at the time the eggs escape is characteristic of the discharge Thus in the intestinal types there is dysentery in the vesical type hematuria

When the schistosome eggs come in contact with fresh water they hatch and the miracidia swim about and seek out appropriate snails which they enter After two fold multiplication within the snails the cercarial progeny emerge usually with the first bright morning s sunshine These larvae possess a forked tail which characterizes their group When the skin of human beings swimming wading bathing or washing clothes comes in contact with infected water (*i e* containing the fork tailed cercariae) the cercariae become attached drop their tails and penetrate under scaling flecks of epidermis or into hair follicles they burrow down to the peripheral capillary beds as the surface film of water drains off The cercariae are then transported through the afferent blood to the right heart and lungs They slowly squeeze through the pulmonary capillaries are carried through the left chambers of the heart and out into the aorta Only those which get into the mesenteric arteries and pass through to the portal vessels survive All others are filtered out as foreign proteins and die Within the intrahepatic portion of the portal blood the successful blood fluke larvae now for the first time begin to feed on whole blood and grow rapidly Approximately twenty days after

are delicate transparent, narrowly oval flukes which parasitize the distal bile ducts especially near the margins of the liver *Clonorchis sinensis* has a wide distribution in Japan Korea China French Indo China and adjacent areas *Opisthorchis felineus* is prevalent in Siberia, East Prussia South eastern Europe and has been reported from French Indo China *O viverrini* has been found only in Northern Siam *Dicrocoelium dendriticum* has been reported as a human parasite from Siberia Europe, North Africa China and Java *Clonorchis* and *Opisthorchis* are contracted from eating raw fish containing the encysted larvae *Dicrocoelium* infection results from ingesting raw grass containing gelatinous masses of pseudo cysts of this worm

Life History—The encysted larvae crawl up the ampulla of Vater to the distal bile ducts and develop into adult worms Here they may live for 15 to 25 years producing hyperplasia of the biliary epithelium a circumscribing fibrosis of the ducts pressure necrosis of the parenchyma and in heavy infections periportal cirrhosis with ascites Light infections are essentially symptomless moderate infections have a progressive development of hepatic dysfunction with loss of appetite a feeling of fulness of the abdomen diarrhea indigestion edema and hepatomegaly heavily infected individuals suffer from catarrhal cholangitis anasarca tachycardia vertigo tremors abdominal cramps and mental depression resulting from intoxication due to reduced liver function

Diagnosis is based on recovery of the characteristic operculate eggs in feces or by duodenal drainage (*Clonorchis* 28 by 16 microns *O felineus* 30 by 11 microns *O viverrini* 26 by 13 microns *Dicrocoelium* 38–45 by 22–30 microns) Care must be exercised not to diagnose as 'positive persons who have eaten sheep livers infected with *Dicrocoelium* Prognosis is good in early light infections poor in heavy or chronic infections There is no eminently satisfactory anthelmintic for any of these infections Prevention consists in thoroughly cooking all fresh water fish (*Clonorchis Opisthorchis*) and greens obtained from moist meadows (*Dicrocoelium*) in endemic foci

Ernest Carroll Faust

PULMONARY DISTOMIASIS

Pulmonary distomiasis is produced by the lung fluke *Paragonimus westermani* a moderately small (7 5–12 by 4–6 by 3.5–5 mm) thick, ovoidal worm which most typically lives in little encapsulated pockets that open into the bronchioles and are almost invariably provided with small blood vessels The infection has a wide distribution in the Far East (Japan Korea, China Formosa French Indo China, Philippines, Siam Malaya portions of India) New Guinea Java Sumatra, parts of Africa (Cameroons Congo Tripoli) Venezuela and possibly Peru and the Matto Grosso area of Brazil

Life History—Eggs (golden brown in color operculate measuring 80–118 by 48–60 microns) are laid by the parent worms into the adventitious capsular pockets and are usually discharged into the bronchiole frequently with flecks of hemorrhaged blood and cellular debris They are coughed up and discharged in sputum or swallowed and evacuated with the feces They embryonate and hatch in fresh water and the miracidial larvae enter appropriate snails After sojourn and two fold multiplication in the snail the emerging cercariae enter the soft tissues of fresh water crabs or crayfishes in which they encyst Man and other crab eating mammals acquire infection from consuming uncooked crab or crayfish meat

Morbid Anatomy—The encysted larvae in the small bowel bore through the intestinal wall traverse the peritoneal cavity bore through the diaphragm and enter the lungs eventually reaching sites near the smaller air passages where they settle down and develop into adults Some of the migrating larvae get sidetracked in the abdomen others in the thorax still others get into the cranium and may wander into the brain or its envelopes The lesions produced (Musgrave 1907) consist of (1) abscesses around eggs infiltrated in host tissue (2) pseudotubercles developed around eggs (3) suppurative and (4) ulcerative processes In the lungs the pathologic picture may consist of generalized or localized diffuse cirrhosis cystic dilatation of the bronchi pneumonitis and tubercle like abscesses with accompanying painful cough and hemoptysis Physical signs may suggest bronchopneumonia or pleural effusion The abdominal

where they become lodged Meanwhile the passage of portal blood through the liver becomes increasingly embarrassed, with compensatory passive and active congestion of the spleen leading to tremendous splenomegaly

Symptomatically there is recurrent daily fever epigastric pain with acute tenderness of the abdominal viscera enlarged tender liver and spleen, and loss of appetite and weight Such an acute episode may terminate in a few weeks but is exacerbated with exercise The blood picture at the initiation of the acute stage is one of leukocytosis with intense eosinophilia later it gradually changes to a leukopenia, with secondary anemia although the eosinophilia remains a prominent feature As the *chronic stage* supersedes the acute period weakness skin pallor and dyspnea on slight exertion become conspicuous Digestion is poor emaciation is evident and the superficial veins of the abdomen and thorax become dilated Depending on the degree of hepatic cirrhosis due to closure of portal radicles by eggs ascites may be a prominent feature Digestion of food now becomes negligible as the intestinal wall becomes thickened and its lumen greatly reduced by cicatricial tissue and papillomata This stage may be prolonged for years or the patient may die of pneumonia or other supervening infectious diseases

On the whole schistosomiasis japonica is a more rapidly developing and fatally terminating infection than schistosomiasis mansoni due to the larger number of eggs layed per female per day and the greater percentage of eggs which reaches the liver and sets up periportal tissue changes Moreover ileitis is more conspicuous in the former infection colitis in the latter In both infections however the average case seen by the physician presents a complex picture of early and late stages due to repeated exposure

Diagnosis in these infections is based specifically on the recovery of the eggs of the respective species in feces In the acute stage these appear in the dysenteric exudate or in flecks of blood and mucus attached to formed or semiformed feces In the chronic stage fewer eggs are discharged and require concentration of the stool for their recovery Repeated sedimentation of a considerable amount of stool after dilution in ten parts of water allows the eggs to settle to the bottom of a cylinder jar or large urinalysis glass so that they may be picked up with a pipette Eggs of *S japonicum* are broadly ovoidal measure 70–100 by 50–65 microns have a moderately thick straw-colored shell to which cellular debris is attached and usually have a motile larva inside Those of *S mansoni* are elongated-ovoidal with a conspicuous lateral spine measure 114–175 by 45–68 microns and are less likely to have cellular elements sticking to the shell surface The history of intestinal and visceral involvement with splenomegaly hepatic cirrhosis with ascites and eosinophilia is suggestive of schistosomiasis although Banti s syndrome must be ruled out

Prognosis is good only in acute and early chronic stages provided adequate specific treatment is carried out

Treatment consists in the administration of antimony preferably fuadin (neoantimosan) intramuscularly in a 6 or 7 per cent solution as follows first day 1.5 cc second day 3.5 cc and beginning with the third day 5 cc every alternate day through the seventeenth (total dosage 40 cc) Frequently several courses of treatment may be required This type of administration is superior to the older tartar emetic or sodium antimony tartrate which requires intravenous administration and usually irritates the bronchial epithelium and results in paroxysms of coughing

Prevention consists in avoiding contact with infected water In localized endemic foci bodies of water may be treated with copper sulfate (1 50 000) to kill the snail intermediate hosts Ultimately control will require that feces of infected persons be mechanically or chemically sterilized with respect to the schistosome eggs before the sewage is discharged into bodies of water in which the appropriate snails develop

ERNEST CARROLL FAUST

VESICAL SCHISTOSOMIASIS

(*Bilharziasis*)

This type of schistosomiasis is commonly due to *S haematobium* rarely to *S mansoni* The pathology and the symptomat

skin exposure the adolescent worms are sufficiently strong to migrate against portal blood out to the mesenteric and vesical venules *Schistosoma japonicum* typically migrates to the superior mesenteric venules draining the small bowel *S mansoni* migrates to the venules draining the large bowel (*i e* colic branch of the superior mesenteric vein and the inferior mesenteric vein) *S haematobium* through the inferior mesenteric vessels and *via* the hemorrhoidals or pudendals into the vesical or pelvic veins The distance of the ultimate habitat of the adult worms from the intrahepatic portal vessels is directly related to the incubation times in *S japonicum* 4 to 5 weeks in *S mansoni* 6 to 7 weeks in *S haematobium* 10 to 12 weeks At the end of the incubation period the worms have matured mated and are beginning to lay eggs

Endemic Regions—Schistosomiasis japonica produced by *S japonicum* has a widespread distribution in the Orient including five small foci in Japan one in Formosa extensive areas throughout the river valleys, lakes and irrigation systems of Central and South China, three or four foci in the Philippines and at least one in Celebes Tens of millions of people in these countries are yearly exposed to infection Schistosomiasis mansoni produced by *S mansoni* has an extensive distribution in Egypt, East, Central and West Africa and in many countries of the West Indies and Northern South America including especially Puerto Rico Venezuela Dutch Guiana and large areas on the northern and eastern coast of Brazil Schistosomiasis haematobia (vesical schistosomiasis bilharziasis) produced by *S haematobium* is common throughout the continent of Africa has been reported from the southern tip of Portugal and is prevalent in Syria Palestine and Iraq

ERNEST CARROLL FAUST

INTESTINAL AND VISCERAL SCHISTOSOMIASIS

These types of schistosomiasis are due to *Schistosoma japonicum* and *S mansoni* and on rare occasions constitute a minor part of the clinical picture produced by *S haematobium*

Clinical Course—The disease may be divided into three stages (1) incubation (2) acute (3) chronic The *incubation period* is initiated by the boring of the cercariae into the skin This rarely causes any considerable degree of trauma or cellular infiltration but is accompanied by a needle like pricking pain at each site of entry While the larvae are squeezing their way through the pulmonary capillaries they frequently rupture the delicate blood vessels and set up an acute cellular reaction at each site with a characteristic infiltration of neutrophils and eosinophils occasionally epithelioid and giant cells Considerable numbers of larvae passing through the lungs may occasion an atypical pneumonia Several days later, after the larvae have reached the portal blood and have begun to feed or have been filtered out elsewhere as foreign proteins there is typically a giant urticaria (especially in white patients) attributed to allergic reaction to the parasites Towards the end of the incubation period the liver becomes enlarged and intensely painful there is indication of generalized intoxication late afternoon temperature and night sweats The final prodromal symptom is a toxic diarrhea

With the initiation of egg laying the *acute stage* is ushered in The eggs work their way through the intestinal wall and escape with blood and necrotic tissue cells with associated tenderness of the bowel wall and dysenteric discharge In schistosomiasis japonica the small bowel is at first primarily involved later the colon in schistosomiasis mansoni the large bowel bears the brunt of the damage Soon many of the eggs freed into the perivascular tissues are not able to make an immediate escape into the intestinal lumen and become the centers for intense cellular infiltration leading to miliary abscesses The shallow abscesses may open into the intestinal lumen but the deeper ones usually become transformed by invasion of epithelioid cells giant cells and fibroblasts into pseudotubercles Gradually there is increased difficulty in the digestion and absorption of food and more extensive open ulceration of the bowel occurs In addition eggs in constantly increasing numbers are carried in mesenteric venous blood back into the liver, where they escape into the periportal tissues and initiate miliary abscesses which later transform into pseudotubercles at each site

Control.—Schistosome dermatitis is relatively prevalent in some of the glacier lakes of Michigan Wisconsin and Northern Minnesota Similar reports have come from Germany France Wales and the Federated Malay States Summer guests in endemic foci especially children should be warned concerning the dangers of exposure and copper carbonate in the amount of $\frac{3}{10\,000}$ pound per calculated cubic foot of infected water should be distributed in water along the shore every two weeks during the guest season to kill the snails in which the cercariae develop

CESTODE OR TAPEWORM INFECTIONS

(*Cestodiasis*)

Cestodiasis is an infection with species of *Cestoidea* (tapeworms) The mature worm (*strobila*) consists of a head (*scolex*) the organ of attachment which is provided with suckers and usually with an anterior complement of hooklets, the "neck" situated immediately behind the head which constitutes the region of growth of the tapeworm and a chain of successive segments (*proglottids*) which arise from the distal end of the neck and become larger and more mature sexually as their distance from the "neck" increases Thus the very young proglottids are designated as *immature* those with fully developed sex organs *mature* and those which serve as storage for eggs *in utero* are the *gravid proglottids* Each mature proglottid is a complete hermaphroditic reproductive unit sexually comparable to a complete trematode The mature egg of human tapeworms contains an embryo within its shell designated as an *onchosphere or hexacanth embryo* Following the onchosphere stage there are one or more larval stages before the worm is ready to develop into the mature strobila Most tapeworms require two or three hosts for the completion of their life cycles

Human tapeworm infections consist of two types

(1) those of which the mature strobila is attached to the bowel wall (*i.e* *intestinal cestodiasis*) and

(2) those for which man is an acceptable larval or intermediate host (*visceral and somatic cestodiasis*)

ERNEST CARROLL FAUST

INTESTINAL CESTODIASIS

Altogether there are thirty or more distinct species of tapeworms which produce intestinal infection in man but only six of these are sufficiently common as human parasites to justify consideration here They are as follows *Taenia saginata* (beef tapeworm) *T solium* (pork tapeworm) *Diphyllobothrium latum* (fish tapeworm) *Hymenolepis nana* (dwarf tapeworm) *H diminuta* (rat tapeworm) and *Dipylidium caninum* (dog tapeworm)

Taenia saginata (*Beef Tapeworm*) — This worm is the largest cestode which infects man A complete strobila measures 12 to 15 feet or more in length and consists of about one thousand or two thousand pro

ology are confined primarily to the bladder and pelvic organs, but there may be considerable pulmonary disease resulting from infiltration of eggs *via* the accessory portal system into the perivascular tissues of the lungs

Clinical Course—The *incubation period* resembles that of intestinal schistosomiasis except that it is more prolonged and never has toxic diarrhea at its termination The *acute stage* is usually ushered in with the painless passage of blood in the urine about three months or more after exposure For months or years there may be no subjective evidence of the disease but sooner or later there is a burning sensation at the time of micturition and increased desire to urinate together with bladder colic and dull pains in the loins and suprapubic region Cystoscopic examination will reveal an inflammatory hyperplasia of the urethra and lower level of the bladder incipient papillomata and concretions of uric acid and oxalates around eggs in the bladder lumen Eggs which have infiltrated into the prostate cause inflammation and fibrosis of this organ The entire bladder wall now studded with pseudotubercles developing around eggs becomes greatly thickened and superficially gritty to the feel although the greater tissue changes are found in the submucosa and muscular layers of the bladder Frequently an endothelial proliferation of the wall of the blood vessels in the area results in multiple thrombosis

The *chronic stage* of vesical schistosomiasis with tissue proliferation and repair begins while egg deposition and extrusion is under way It is characterized by increasing lodgement of the eggs in nearby tissues with multiple abscess and pseudotubercle formation leading to hyperplasia and fibrosis of the entire bladder wall This is frequently accompanied by invasion of streptococci and staphylococci which greatly complicate the picture Thus a condition of chronic cystitis is reached Cystoscopic examination now becomes difficult bladder calculi develop the urethra may become occluded and an intermittent, frequently uncontrolled discharge of urine blood pus and eggs ensues Pyogenic invaders may extend the lesions to the periurethral or perivascular areas or fistulas may extend into the rectum or scrotum Malignancies of the involved tissues are not infrequent The patient becomes incontinent and usually succumbs to extensive dysfunction of the urinogenital system.

Diagnosis consists in the recovery of eggs from the sediment which settles out at the bottom of a urinalysis glass into which the patient has passed a specimen These eggs of *S haematobium* are elongated-ovoidal with a distinct terminal spine measure 112-170 by 40–70 microns, are pale yellow with a moderately thick wall, house a fully developed motile larva and frequently have cellular debris adherent to the shell

Prognosis is relatively good except in the terminal stage provided specific treatment is administered

Treatment consists in the administration of fuadin (neoantimosan) as recommended for intestinal schistosomiasis (*vide supra*) Prevention is similar to that of the intestinal types except that urine is the source for infection of the appropriate snails

Ernest Carroll Faust

SCHISTOSOME DERMATITIS

The fork tailed larvae (cercariae) of several species of nonhuman blood flukes (schistosomes) have been found capable of penetrating the skin of persons wading or bathing in 'infected fresh water with resulting *schistosome dermatitis*

Symptoms—As the infected' water drains off or evaporates from the victim's skin the cercariae penetrate below the epidermis and for a week or more may remain alive in the deeper skin layers It is even possible on the basis of experimental evidence that in small children these larvae may get through the blood stream to the lungs At the time of skin penetration there is a prickling sensation with macule formation followed by urticarial wheals and modification of the macule into a papule Within a few hours to two to three days later intense pruritus of the involved areas is experienced with a marked edema and transformation of the papule into a pustule Scratching of the itching areas frequently produces sepsis Palliatives as calamine lotion should be applied to the involved skin areas and attempts should be made to prevent secondary bacterial invasion

with four suckers and an anterior circlet of hooklets The distalmost proglottid disintegrates in the small bowel, setting the characteristic eggs free These eggs are nearly spherical measure 30 to 47 microns in diameter have a hyaline outer shell and an inner shell provided with a pair of polar thickenings and polar filaments The presence of these filaments is species diagnostic These eggs when evacuated in human stools require no intermediate host If accidentally taken into the mouth of the same or another human being and then swallowed they hatch and develop to the mature worms although a brief sojourn in the stroma of the intestinal villi is required for the transformation of the six hooked embryo into a larval stage This infection is much more prevalent in children than in adults and tends to be familial or institutional in its distribution Worms morphologically indistinguishable from *H nana* are common parasites of rats and mice but are physiologically distinct Hence human infection is of human origin The infection is cosmopolitan but is especially common in the Southern Appalachian area of the United States

Hymenolepis diminuta (*Rat Tapeworm*) **and Dipylidium caninum** (*Dog Tapeworm*) —These tapeworms are relatively uncommon in man although at least 200 authentic cases of the former and several dozen cases of the latter have been reported from the human host The intermediate hosts for these species are insects frequently fleas ectoparasitic respectively on rats or mice and dogs or cats Human infection results from accidentally ingesting infected intermediate insect hosts

Symptoms —The pathogenicity and symptomatology of tapeworm infections probably do not differ intrinsically with the species of tapeworms involved but depend on several factors including the number and mass of the worms trauma and ulceration produced at the sites of attachment to the wall of the small intestine host reaction to toxic by products of the worms and probably constitutional reactions of the host Except for *H nana* it is common to have only a single tapeworm present in the small bowel However although a fifteen foot *T saginata* may fill a 2 liter container many adult patients who harbor such a parasite have no subjective symptoms resulting from the infection On the other hand some persons are extremely sensitive to the presence of a single *H nana*

Clinical Course —An average history of a patient harboring *T saginata* or *T solium* or *Diphyllobothrium latum* is as follows Towards the end of the three month incubation period following the consumption of essentially raw beef or pork or fresh water fish there are a toxic diarrhea and false hunger pains at times systemic toxemia During the early acute stage there is a moderate leukocytosis with an eosinophilia not in excess of 13 per cent There may be diarrhea alternating with constipation After several weeks the average patient will have no apparent evidence of the infection except the almost daily annoyance of proglottids crawling out of the anus and frequently down the leg There may be a mild microcytic or normocytic anemia later a moderate leukopenia In other patients parasitized by *T saginata* or other intestinal tapeworms there may be abdominal colic with or without diarrhea, anorexia loss of appetite and weight insomnia extreme weakness nervousness convulsions in children pronounced anemia of a normocytic or macrocytic type (especially in *D latum* infection)

Diagnosis consists in recovery of the characteristic gravid proglottids in the feces or migrating out the anus less commonly eggs in the feces (*T saginata T solium D caninum*) recovery of the eggs consistently in the feces (*D latum H nana H diminuta*) Prognosis is usually good especially with specific treatment

Treatment —There are several anthelmintics which have been used with success for the evacuation of intestinal tapeworms The writer s experience favors the oleoresin of *Dryopteris* (*Aspidium filix-mas*) Routine treatment involves semi starvation the day before treatment and before going to bed that night taking one ounce (30 cc) of Glauber salts dissolved in a glass of water On the morning of treatment the patient remains in bed takes no food or drink except water (or black coffee) and at 7 00 a m 7 30 a m and 8 00 a m each takes 20 minims of fresh oleoresin aspidii in cap

glottids The "head' is small quadrate-rhomboidal, possesses four deeply excavated suckers but lacks an anterior circlet of hooklets The neck" region is delicate, narrow, and measures a centimeter or more in length Immature and mature proglottids constitute approximately the proximal half of the strobila the gravid ones make up the distal half The uterus of the gravid proglottid consists of a long median longitudinal tube with fifteen to twenty one (usually eighteen) main lateral rami on each side of the main stem Each uterus contains myriads of characteristic eggs each consisting of a walnut colored hull like spherical shell 31 to 43 microns in diameter, and inside the six hooked embryo While eggs of this worm are at times shed inside the human bowel usually the distalmost gravid proglottids, singly or in chains break off from the parent worm and are passed in feces or actively migrate out the bowel Cattle the only known intermediate host pick up the eggs when grazing on moist pastureland contaminated with human sewage The embryos hatch in the ox's small bowel migrate to striated muscle and in three months metamorphose into the mature bladder worm larvae (*Cysticercus bovis*) When man consumes this infected meat inadequately cooked he acquires the infection which requires about three months for incubation This infection is prevalent throughout countries where individuals eat essentially raw beef

Taenia solium (*Pork Tapeworm*) —This tapeworm resembles *T saginata* with the following exceptions It seldom reaches ten feet in length and consists of less than one thousand proglottids The head is armed with a circlet of hooklets anterior to the suckers the 'neck is relatively short and stout the gravid proglottids have a uterus with only seven to thirteen (usually nine) main lateral rami on each side of the main stem The eggs however are indistinguishable from those of *T saginata* and usually escape from the human body in unbroken gravid proglottids Hogs which feed on human feces become infected and within three months the bladder worm larva or pork measle (*Cysticercus cellulosae*) is fully developed in their striated muscle Man becomes infected from eating inadequately cooked pork This infection is uncommon in the United States but is common in Eastern and Southeastern Europe and in many countries of Asia

Diphyllobothrium latum (*Fish Tapeworm*) —This tapeworm is unlike any other common tapeworm of man in many respects It has a narrow spatulate 'head' which is provided only with a pair of longitudinal grooves or sulci for purpose of attachment The strobila may reach several feet in length but never develops strictly gravid proglottids In each mature proglottid there is a patent uterine pore through which immature eggs are discharged soon after they are produced These eggs are therefore always recoverable from feces They are broadly ovoidal measure about 70 by 45 microns are straw colored and possess an operculum at one end When infected human stools are discharged into bodies of fresh water the eggs mature the operculum of each egg opens and ciliated six hooked embryos escape into the water If these swimming embryos are eaten by 'water fleas (*Diaptomus* or *Cyclops*) they develop to the first larval stage in the hemocelic cavity of the water flea' When fresh water fishes eat the infected fleas they become infected with the second larval stage which matures in the flesh of the fish The infection is now ready for man if he eats infected raw fish However the fishes which commonly ingest 'water fleas are usually too small for human food but when these smaller fishes are eaten by larger game fish, the flesh of the latter constitutes the source of human infection *D latum* infection is mostly if not exclusively confined to the North Temperate Zone It is common in Northern Central and Southeastern Europe in many parts of the U S S R Japan the lake districts of Central South Canada and the northern portions of Minnesota and Michigan In the Western Hemisphere it is particularly prevalent in Scandinavian peoples and in Polish Jews Iced fish which is shipped from endemic foci to many urban centers in the United States has provided the source for numerous infections

Hymenolepis nana (*Dwarf Tapeworm*) —This is a minute worm only a few centimeters long and is correspondingly small in other dimensions Its head is provided

or its envelopes cysticerci provoke critical lesions which interfere with important functional processes Possibly little damage may result in these foci until the larvae begin to die whereupon there is an intense cellular infiltration in the area at first inflammatory in nature later fibroblastic in an attempt to wall off the toxic process Thus the tumor mass is appreciably increased The most common site for these damaging lesions is within the brain tissues provoking a Jacksonian type of epilepsy Moreover there is cumulative evidence indicating that persons with subcutaneous or muscular cysticercosis usually develop epileptiform seizures as a result of brain lesions

Treatment —There is no satisfactory treatment for most of these brain cases although occasionally it is possible to remove the intracranial tumor Meticulous personal hygiene is indicated in areas where *Taenia solium* is prevalent

Coenurosis —Related to cysticercosis is the rather rare condition of coenurosis infection with the larval stage of certain tapeworms of the genus *Multiceps* Usually the larvae develop in sheep hogs or rabbits occasionally in man

ERNEST CARROLL FAUST

ECHINOCOCCOSIS

(*Hydatid Disease*)

Echinococcosis or hydatid disease is caused by the larval stage (*i e* hydatid cyst) of the tapeworm *Echinococcus granulosus* of which the dog is the common definitive host and sheep hogs cattle and man the most usual intermediate host

Life History and Morbid Anatomy —The mature worm is a minute organism only a few millimeters long and consists typically of a head a neck a single immature a single mature and a single gravid proglottid The worms live attached to villi or in the glandular crypts of the small intestine The gravid proglottid disintegrates setting *Taenia* like eggs free in the bowel s lumen so that they are evacuated in dog s feces Whenever these eggs contaminate food or drink or otherwise get into the mouth of a susceptible mammal and are swallowed they hatch in the duodenum and the six hooked embryos gain entrance to the bowel wall They reach the mesenteric venules or lymphatics and are filtered out in various foci

In man 70 per cent of the organisms lodge in the liver increasingly smaller percentages in the lungs osseous tissues brain and other tissues of the body On reaching the site where they are filtered out the six hooked embryos transform slowly into minute vacuolated cysts then as they gradually increase in size they are found to have an inner germinative membrane an outer laminated layer and usually a fibrous adventitious capsule The cystic cavity is filled with hydatid fluid The size of the cyst is limited only by its physical and mechanical confines Thus in five years or more an hepatic hydatid cyst may average from 5 to 25 cm in diameter From the germinative membrane multiple scolices or heads (*hydatid sand*) are produced and set free into the fluid filled cavity These scolices vacuolate and develop into daughter cysts Such a mother cyst is viable and is termed *unilocular*

At times the original implantation of the hexacanth embryo is in a site mechanically incompatible with unilocular growth Scolices from the germinative membrane then migrate through the laminated layer and reach the unconfined host tissue through which they multiply and metastasize as *alveolar hydatids* If the scolices reach the spongy tissue of bones the organism develops as a syncytium eroding its way as an *osseous hydatid*

Endemic Regions —Echinococcosis is widely distributed over the face of the earth but is particularly prevalent in sheep raising countries Human infection has an extensive distribution in Central Southern and Eastern Europe the Near East the U S S R China and Japan the North Coast of Africa and South Africa However the disease is of greatest human importance today in Australia New Zealand Argentina and Uruguay in which countries it is a major public health problem In the United States there were previously many case reports of hydatid cyst mostly from immigrants from Eastern Europe Today the number is diminished but several native-born patients are diagnosed each year and

sules or on a spoon with sugar At 10 a m Glauber salts purgation is repeated No food is allowed until copious post treatment bowel movements have been obtained All stools passed for a period of at least twenty-four hours after medication are examined for the 'head' of the worm Unless the 'head is recovered there is no proof that the worm has been eradicated and the "head" may (and usually does) develop a complete new worm in three to four months

Two valuable *alternative methods* of administering oleoresin aspidii are as follows To 4 cc (60 minims) fresh oleoresin aspidii add 30 cc (one ounce) mucilage of acacia and 30 cc (one ounce) sat sol Glauber salts Either administer this emulsion by mouth or by transduodenal intubation to the patient prepared by pre treatment purgation For this method of procedure no post treatment purgation is required

Some physicians prefer *carbon tetrachloride* for removal of intestinal tapeworms The drug is given in capsules in the amount of 3 cc (45 minims) at one administration in the morning with pretreatment fasting and post treatment, precautionary measures as outlined above Although very efficacious this anthelmintic is probably somewhat more toxic than oleoresin aspidii However, the main criticism of its use is its destructive action on the entire tapeworm making it almost impossible from examination of the post treatment stools to discover if the 'head has been evacuated

For children harboring the dwarf tapeworm (*Hymenolepis nana*) it may be advisable to try caprokol (hexylresorcinol crystoids) before utilizing the more toxic specifics Pretreatment Glauber salts purgation is indicated the night before treatment In the morning in a single dose on an empty stomach caprokol is administered in hard gelatin capsules as follows for children of preschool age 0 4 Gm (6 grains) for children six to ten years 0 6 to 0 8 Gm (10–12 grains), for those over ten years the adult dosage of 1 0 Gm (15 grains) Glauber salts purgation is recommended two hours later and food is proscribed for four to five hours

ERNEST CARROLL FAUST

VISCERAL AND SOMATIC CESTODIASIS

Under this group of diseases are included cysticercosis, echinococcosis (hydatid disease) and sparganosis

ERNEST CARROLL FAUST

CYSTICERCOSIS

Cysticercosis is infection with the larval or bladder worm stage of a species of *Taenia* There are on record only two cases of cysticercosis of man referable to the beef tapeworm *T saginata* in contrast there are thousands of published clinical and necropsy reports of human cysticercosis cellulosae (due to the pork tapeworm *T solium*)

Life History —There is thus overwhelming evidence that man is an acceptable intermediate host of *T solium* as well as the only known definitive host of this worm. How then does man become infected? There are three possible methods (1) he may accidentally take into his mouth and swallow the eggs of *T solium* passed in the stools of someone else harboring the intestinal worm (2) he himself may harbor the intestinal worm and by anus to mouth contamination may ingest the eggs (3) he himself may harbor the intestinal worm and by regurgitation eggs discharged from gravid proglottids may be carried up into his stomach then returned to his duodenum Whichever the method is by which the eggs reach the upper levels of the human small bowel they will hatch and the six hooked embryos migrate through the bowel wall into the mesenteric venules or lymphatics They are then carried to all tissues of the body where they lodge and develop into cysticerci within three months Unlike the situation in the pig where essentially only striated muscles are involved in man the cysticerci can become implanted on and develop in any body tissue including muscle subcutaneous layers the heart valves the orbit and the ventricles tissues or envelopes of the brain

Symptoms and Morbid Anatomy —The presence of a few to hundreds of cysticerci in the subcutaneous tissues and somatic muscles produces only slight inconvenience and is essentially painless On the heart valves in the orbit or in the tissues of the brain

THE NEMATHELMINTHES

(*Roundworms*)

THE NEMATHELMINTHES include the Class NEMATODA or True Roundworms the Class GORDIACEA and possibly other groups The Class NEMATODA contains all of the Roundworms of special medical importance

NEMATODA (True Roundworms or Nematodes) are elongated frequently cylindroidal invertebrates with a cuticula which may be smooth but is at times provided with spines or hooklets particularly around the mouth There is a complete digestive tract consisting of a buccal cavity muscular esophagus mid gut and rectum In the male the rectum opens into a cloaca in the female directly to the outside through an anal pore The body cavity is not lined with epithelium The excretory system lacks any evidence of cilia The sexes are usually separate but syngony (i e male organs in the female worm) occurs in a few species and parthenogenesis in a few others The sex organs are greatly elaborated and occupy the major part of the body cavity Most nematodes are oviparous but a few are larviparous (i e *Trichinella spiralis*) Some eggs are fully embryonated when laved others require a period of incubation outside the human body Some eggs hatch in the soil grow and metamorphose into infective stage larvae Some nematodes require an intermediate host for completion of their larval development Filaria worms are taken up as prelarval *microfilariae* from the peripheral blood vessels or tissues of man by a blood sucking insect in which host they transform into larvae that become infective and are then introduced into or onto the human skin when the insect takes its next blood meal from man Man acquires most nematode infections by the oral route but hookworm and *Strongyloides* larvae actively invade the skin and filaria larvae gain entrance into the skin after escape from their blood sucking insect hosts

The following important nematode infections of man will be considered here trichinosis trichocephaliasis strongyloidiasis creeping eruption ascariasis oxyuriasis filariasis and dracunculosis (For hookworm disease *vide* p 423)

ERNEST CARROLL FAUST

TRICHINOSIS

(*Trichiniasis*)

Trichinosis is produced by *Trichinella spiralis* the trichina worm

Life History —These parasites gain entry to the human body when raw or inadequately cooked pork (rarely bear meat) containing the encysted larvae is eaten most commonly in the form of sausage Excystation of the larvae takes place in the stomach or duodenum and the larvae immediately enter the superficial part of the mucous membrane of the duodenum or jejunum In three or four days the worms have matured have mated and by the fifth day the female is beginning to discharge living young At first some larvae escape into the lumen of the bowel and are evacuated in the feces but as the females migrate nearer to the muscularis mucosae the larvae in

increasing numbers gain entrance to the mesenteric lymphatics and venules and are carried throughout the body, finally settling down in skeletal muscle, where they soon become encysted In the human body this ends their life cycle although they may remain viable for many years In the reservoir host as the hog the encysted larvae constitute the source of infection for the next host Thus in nature a susceptible host harbors all stages in the life cycle of the worm but the infection cannot be propagated unless infected flesh of that host is eaten raw by the next host

Endemic Regions —Trichinosis in man is practically world wide in its distribution wherever hogs are eaten as food but it is rare in some tropical countries Its prevalence in the United States has been emphasized in recent years due to increased recognition of its presence and possibly increased incidence in the human population Autopsy examinations and immunologic tests of the living population indicate that the infection is present in man even if inapparent in all areas of the United States which have been investigated At times mild to severe epidemics of clinical grade have developed due to eating heavily parasitized pork

Clinical Course —Pathologically and symptomatically there are three stages in the disease paralleling the three biologic stages of the parasite, namely (1) the stage of invasion (2) the stage of migration of the larvae and (3) the stage of encystation During the first few days when the excysted larvae are migrating into the duodenal and jejunal mucosa they cause considerable trauma and irritation to the mucosal cells with clinical manifestations simulating acute food poisoning such as nausea vomiting and diarrhea There may be a bright macular or papular eruption on the skin With the beginning of larviposition and larval migration and infiltration of the larvae in the muscles excruciatingly painful myositis is initiated and continues for five or six weeks, resulting from inflammatory reaction wherever the larvae pass This acute reaction is particularly evident in the muscles of respiration speech mastication and swallowing while spastic paralysis of the muscles of the extremities is not unusual Edema especially around the eyes nose and temples accompanies this stage A remittent temperature of 40-41° C (104-105 8° F) is characteristic The blood picture shows a hypereosinophilia with leukocytosis Thrombi in the blood vessels of the viscera or extremities, adenitis, encephalitis and meningitis, ocular disturbances deafness and many other functional disturbances indicate the protean character of the lesions With encystation of the larvae the critical stage of intoxication and sequelae to the earlier tissue damage begins There may be cachexia toxic edema or extreme dehydration Nervous disorders may simulate almost every type of hallucination, mania paralysis or hyperactivity, which usually are transitory but may be permanent In severe fatal cases the pulse is at first fast and strong then weak and cyanosis supervenes The patient may succumb to toxemia to a hypertensive myocarditis resulting from the damage produced by trichina larvae migrating through the myocardium to pneumonia peritonitis, pleurisy and especially to acute nephritis

The above picture is that of the heavily infected individual small groups (rarely larger groups) of which give a history of having eaten pork (country or European style sausage) from a single source Most clinical cases are milder and the great majority of patients have infections below the clinical grade This last type probably has eaten raw or inadequately cooked sausage put up in a large packing plant in which meat of one infected hog was pooled with that of many uninfected ones thus greatly diluting the dose

Diagnosis may be suspected in a patient who gives a history of acute food poisoning following the consumption of pork sausage with sequelae of excruciatingly painful muscular rheumatism While larvae may at times be recovered from diarrheic stools or from centrifuged blood samples specific diagnosis is usually not made until encystation has occurred (ten days or more after exposure) Biopsied deltoid biceps or gastrocnemius muscle strips (1-5 Gm) digested for a few hours in artificial gastric juice at 37° C will provide evidence of motile larvae The most valuable laboratory test is the Bachman intradermal reaction (Bachman 1928

Augustine and Theiler 1932) using 1 5 000 to 1 10 000 dilution of antigen)

Prognosis is good in mild infections but poor in heavy infections particularly if there is no eosinophilic reaction

Treatment consists of supportive and palliative measures The bowels should be kept open and alkalinized and in so far as possible normal kidney function should be carefully maintained Sedatives should be utilized during the stage of muscular pain Cardiac and respiratory stimulation may be indicated Sterile physiologic saline infusions may be administered by hypodermoclysis for dehydrated patients

Prevention consists on the one hand of the thorough heating of all pork intended for human consumption unless previously frozen at —15° C (5° F) for twenty days or at —18° C (—0 4° F) for twenty four hours More far reaching is the need for regulations to prevent the feeding of raw garbage (containing infected pork trimmings) to hogs on the farm or in fattening pens together with extermination of rats and mice in hog raising areas

Ernest Carroll Faust

TRICHOCEPHALIASIS

(*Trichuriasis Whipworm Infection*)

This is an infection with the whipworm *Trichocephalus trichiurus* (syn *Trichuris trichiura*) and involves primarily the cecum and appendix

Life History—The adult worms measure 30 to 50 mm in length have a delicate thread like anterior half and a fleshy posterior half The females have a club shaped posterior extremity the males a flatly spiralled posterior end The anterior end of the worm is inserted or basted into the mucous membrane of the parasitized level of the bowel wall The female lays daily a few thousand bilaterally symmetrical barrel shaped eggs (measuring 50–54 by 22–23 microns), which are usually bile stained and have a blister like plug at each pole These eggs are unembryonated when evacuated in feces On moist shaded warm earth they develop in ten to fourteen days to the infective stage Upon being swallowed they hatch in the duodenum the emerging larvae slowly migrate down to the cecum or appendix become attached and in about three months after ingestion develop to the adult stage The infection is relatively cosmopolitan in all except cold climates but is dependent on moist earth for the extrinsic incubation of the eggs Heavy infections are most frequent in the moist Tropics Children are more commonly exposed than are adults

Symptoms—Mild infections (*i e* with low worm burden) such as usually obtained in the Southern United States seldom produce a distinct train of symptoms even though it has been demonstrated that there is microscopic pathology around the heads of the worms in the bowel wall Nevertheless children are occasionally intolerant of whipworms even in small numbers as indicated by an eosinophilia of 8–25 per cent loss of appetite insomnia nervousness loss of weight urticaria and rarely convulsions In heavy infections (*i.e* several hundred worms) the clinical picture is that of severe hookworm disease Nevertheless the profound secondary anemia of heavy whipworm infection cannot be attributed to mechanical loss of blood from the intestinal mucosa as in hookworm infection and its etiology remains unexplained

Diagnosis of trichocephaliasis depends on the recovery of the characteristic eggs in the feces of the patient Concentration technics as with brine or zinc sulfate centrifugal flotation may be required to apprehend eggs in mild infections Prognosis is good except in heavy infections or those to which children show marked intolerance to the parasite

Treatment with available anthelmintics is not particularly effective Repeated weekly administrations of caprokol by mouth 0 4–1 0 Gm (6–15 grains) on an empty stomach preceded and followed by Glauber salts purgation (1 ounce or 30 Gm in a glass of water) is helpful in evacuating the majority of the worms As an alternative 2–3 cc (30–45 minims) of tetrachlorethylene in 0.5 or 1 cc globules may be prescribed with pre- and post treatment Glauber salts purgation However since effectiveness of these drugs in eradicating whipworms depends on the drug coming in direct contact with the worms in the cecum or appendix pretreatment enemas to wash out these levels of the

bowel is recommended In Central and South America a crude anthelmintic, *leche de higueron* obtained from the trees *Ficus glabrata* and *F doliana*, has specific action on this worm Unfortunately this product ferments readily, its effective fraction "ficin" is unstable and thus far it has not been available for use in the United States

Prevention consists in care not to contaminate food drink or fingers with soil containing embryonated eggs

Ernest Carroll Faust

STRONGYLOIDIASIS

(*Strongyloidosis*)

Strongyloidiasis is produced by *Strongyloides stercoralis*, a delicate roundworm which is of extraordinary interest biologically and epidemiologically because it exhibits capacities for complete parasitic existence on the one hand and complete free living existence on the other

Life History—The adult parasitic worms are primarily parasites of the intestinal tract. The parasitic male when found is tenuously attached to the mucous membrane of the bowel predominantly at the level of the duodenum Usually within a month after arrival at this site the male has been carried down the bowel and evacuated in feces The delicate thread like female measuring about 1 mm in length by 50 to 75 microns in diameter is typically buried in the mucosa of the bowel wall most commonly at the level of the duodenum but heavy infections may extend from the pyloric wall of the stomach to the anus Within the mucous membrane these worms lay partially embryonated eggs resembling those of the hookworms Embryonation is completed in the glands and villi of the bowel and hatching takes place here The escaping first stage (*i e* rhabditoid) larvae burrow out to the lumen of the bowel are passed down and evacuated in feces If the feces are deposited on moist, shaded, sandy humus in a favorably warm climate the rhabditoid larvae feed grow, moult and metamorphose into post feeding *filariform larvae*, which are the infective stage

Morbid Anatomy—On contact with exposed human skin, these larvae penetrate under the epidermis and down to the cutaneous blood capillaries On gaining entry to the afferent blood vessels the organisms are carried through the chambers of the right heart to the lungs They burrow out of the pulmonary capillaries into the air sacs, slowly migrate up the respiratory tree crawl over the epiglottis and are swallowed Meanwhile they have grown in size have become adolescent and by the time they have reached the level of the duodenum have become sexually differentiated If males are present fertilization of the females may occur before they enter the mucosa but there is considerable evidence that the females are able to produce parthenogenetically Within twenty eight days after skin exposure egg laying begins Should larvae be blocked in the air sacs or bronchioles by cellular infiltration the worms continue to grow in these sites and the females may burrow into the bronchial epithelium and establish foci of infection there The above life cycle is the most frequent and is referred to as the *direct mode of development* In favorable warm climates however the rhabditoid larvae evacuated in human stools onto moist ground develop into free living rhabditoid adults which mate lay eggs and continue through one or more free-living generations Eventually, however and usually after one such extrinsic cycle, filariform larvae are produced and the parasitic phase is again established This alternation of parasitic and free living cycles is the *indirect mode of development* A third type of development an insidious and dangerous one for the host is *autoinfection* In some patients usually chronically infected with *Strongyloides* rhabditoid larvae *en transit* down the bowel or lodged in moist feces on the perianal skin become transformed into filariform larvae and are enabled to penetrate the mucous membrane of the intestine or the perianal skin and thus initiate superinfection without having left the host In rare instances rhabditoid larvae metamorphose into filariform larvae without leaving the intestinal mucosa However in all cases these larvae must make a "lung journey" before they can mature in the intestinal wall Internal autoinfection is called *hyperinfection*

Endemic Regions—Strongyloidiasis is apparently coincident with hookworm infection over the face of the globe being most prevalent in the moist Tropics However the relatively meager data on exact distribution and incidence indicate that strongyloidiasis is limited to a more delicate adjustment of extrinsic conditions There are no important reservoirs of this infection

Pathology—The pathology produced by *Strongyloides stercoralis* consists of trauma due to the slow migration of the parasitic female in the intestinal mucosa the escape of eggs into the glands and stroma and the burrowing of hatched rhabditoid larvae Typically the damage involves only the mucosa and does not extend into the submucosa At times cellular encapsulation of adults eggs and larvae occurs but the usual cellular reaction is an infiltration of polymorphonuclear and eosinophilic leukocytes around the worms Irritation of the mucosal cells causes a mucositis and from time to time little patches of necrotic mucosa are sloughed off leaving denuded areas If the infection is extensive there is a mucous watery diarrhea which may alternate with constipation and be reactivated at times of dietary indiscretions or overexertion In heavy infections dehydration may be extreme

Symptoms—Epigastric pain is the most common subjective symptom There is a hypereosinophilia (up to 40 per cent or more) with leukocytosis during the acute stage followed by a leukopenia with a somewhat reduced eosinophilia As the chronic stage develops the fecundity of the female worms may decrease or the worms may become partially encapsulated so that larvae are fewer in the stools and more difficult to discover Meanwhile the patient tends to become toxic, develops dull headaches and periods of despondency Although the parasitic females possibly live for only a year or two the infection may be perpetuated by autoinfection Patients who have been studied by the writer over more than ten years have had persistent infection in spite of the impossibility of a new external source of inoculation *Strongyloides* pneumonitis may also complicate the picture

Diagnosis consists in the discovery of typical rhabditoid larvae occasionally filariform larvae usually in loose or diarrheic stools at times coughed up in sputum These must be differentiated from similar stages of hookworm which may develop in feces left standing in the diagnostic laboratory Hypereosinophilia with a history of diarrhea is relatively pathognomonic The prognosis is fair to good in mild early cases given the benefit of specific therapy poor to grave in severe cases left untreated Absence of eosinophilia is a poor prognostic sign

Treatment consists in the adequate administration of gentian violet medicinal first advocated in the United States by the writer in 1930 For the average adult case one grain (0 06 Gm) is given with meals three times daily (two 0.5 grain Seal Ins or Enseals 1½ hr coating) until 50 grains have been taken One or two such courses of treatment produce cure in about 90 per cent of *Strongyloides* patients For refractive cases and those which develop intestinal colic from taking the enteric coated tablets transduodenal intubation of 25 cc of a 1 per cent solution of the drug is quite effective The rationale of treatment consists of the deep staining of the mucous membrane of the intestine particularly that of the duodenum (hence 1½ hr coating) down to the muscularis mucosae to reach all of the worms Sometime during the administration of the enteric coated tablets and following transduodenal intubation nausea and vomiting may be expected If pulmonary strongyloidiasis occurs intravenous injection of 0.5 per cent solution of filtered gentian violet medicinal may be given to hospitalized patients in amounts not to exceed 20 cc each every alternate day for one month

Prevention consists in care not to walk bare-footed or otherwise expose the skin to polluted soil in the sanitary disposal of human feces and in adequate treatment of detected cases until they have been cured

ERNEST CARROLL FAUST

CREEPING ERUPTION

Creeping eruption is a dermatitis produced by invasion into the deeper layers of the skin by nematode or fly larvae which continue to migrate for weeks or months through serpiginous tunnels in the stratum

germinativum The etiologic agent has in years past been referred to as larva migrans" Among the nematode larvae the hookworm *Ancylostoma braziliense* is most commonly incriminated Filariform larvae of canine and feline strains of *A braziliense* unlike human strains of this species or the other human hookworms on contact with human skin are unable to negotiate an entry into the cutaneous blood vessels However, they progress intracutaneously at the rate of several millimeter to a few centimeters per day producing an inflamed elevated tunnel which becomes vesicular and frequently is complicated by invasion of pathogenic bacteria There is an intense pruritus of the involved area almost invariably provoking scratching This infection is distributed throughout the coastal areas of the Southeastern and Gulf States especially in Florida but occurs elsewhere in warm climates The foot is most frequently involved but any other area of the skin which comes in contact with moist sandy soil where *A braziliense* infected dogs or cats have previously defecated is readily subject to infection

Another nematode whose larvae cause creeping eruption is *Gnathostoma spinigerum* with a distribution in the Orient and the South Pacific The lesions of gnathostomiasis may be similar to those described for *A braziliense* or may be more like cutaneous abscesses

Creeping eruption produced by fly larvae (*i e maggots*) is a dermal myiasis and is due primarily to skin invasion by maggots of the horse bot *Gasterophilus* Eggs are layed on the human skin hatch and the maggots penetrate down to the stratum germinativum or corium then travel in this layer for weeks or months like *A braziliense* larvae Differential diagnosis can readily be made by massaging the involved site with clear machine oil If numerous black bands (of spines) are seen with a hand lens the agent is *Gasterophilus*, otherwise most likely it is *A braziliense* Prognosis is good if septicemia is avoided

Treatment —Recommended treatment for *A braziliense* creeping eruption is the application of ethyl chloride spray to freeze the site at the inner end of the tunnel where the larva resides, for *Gasterophilus* it consists of removing the larva with a sterile sharp needle, and dressing the wound with mild antiseptic bandages

Prevention —Control of creeping eruption of hookworm origin consists of avoiding skin contact with sites where dogs or cats have defecated For *Gasterophilus* intensive campaigns to eliminate horse flies should be instituted

ERNEST CARROLL FAUST

ASCARIASIS

Ascariasis is produced by the large roundworm *Ascaris lumbricoides*, which inhabits the lumen of the small bowel The worm is elongate cylindroidal, and tapers bluntly at the anterior end and to a moderately sharp point posteriorly The head is provided with three conspicuous fleshy lips surrounding the triangular mouth The males average 15 to 31 cm in length by 2 to 4 mm in diameter the females 20 to 35 cm by 3 to 6 mm The male is curved ventrally at the posterior extremity

Life History —Females lay up to 200 000 eggs each per day These may be infertile or fertile The former are more elongated and have a disorganized mass of granules and globules completely filling the inner shell The fertile eggs are broadly ovoidal measure 45–75 by 35–50 microns have a spherical heavily granular unsegmented egg cell a thick hyaline inner shell and a thick mammillated usually bile stained outer shell When evacuated in human feces onto the ground they proceed to embryonate and in nine days or more will contain a motile rhabditoid larva coiled inside In another week this unhatched larva sheds its cuticle and now becomes infective It remains infective for months and possibly years Only direct sun s rays or heat will kill the embryonating or infective stage egg When human beings pick up these mature eggs on their fingers or otherwise get them into their mouths and swallow them the eggs hatch in the duodenum or jejunum and the emergent larvae enter the intestinal wall and make their way to the lungs *via* the mesenteric lymphatics or venules vena cava right heart and pulmonary arteries They break

out of the pulmonary capillaries into the air sacs, migrate up the respiratory tree crawl over the epiglottis are swallowed and in sixty five or seventy five days after exposure become adult worms in the lumen of the small intestine

Endemic Regions —Ascariasis is cosmopolitan in its distribution but is more prevalent in warm than in cold climates Its epidemiology differs materially from that of hookworm disease or oxyuriasis The soil is seeded with *Ascaris* eggs passed in feces of infected individuals Primarily this is the result of promiscuous defecation by small children in and around the home (Cort 1931) These same children and their associates later on become exposed to new infections when they pick up eggs that have become fully embryonated Thus infection in an environment tends to become endemic and infected individuals may at one and the same time harbor adult egg laying *Ascaris* and young worms in the intestine as well as larvae *en route* through the lungs

Morbid Anatomy —The first important lesions produced in ascariasis are in the lungs due to the breaking out of the migrating larvae from the pulmonary capillaries into the air sacs These rhabditoid larvae are considerably more robust than the migrating filariform larvae of hookworms and *Strongyloides* and produce more trauma and hemorrhage In considerable numbers they cause small pools of extravasated blood to accumulate in the air sacs provoking polymorphonuclear infiltration and resulting in an atypical lobular pneumonia which constitutes a distinct clinical entity *Ascaris pneumonia* especially in small children In the small bowel adolescent and adult ascarids may produce no apparent disturbance even when present in moderate numbers In the absence of reinfection the worms will be passed spontaneously or die within the bowel in approximately a year s time Digestive upsets or other abnormal conditions within the bowel will frequently irritate these worms and provoke activities hazardous to the patient They may be regurgitated and vomited or escape through the external nares they may block the common bile duct or the appendiceal lumen setting up acute inflammatory processes or may perforate the intestinal wall and initiate peritonitis The most common complaint in *Ascaris* patients is intestinal colic Rarely the worms have been found in the parenchyma of the liver and in the pleural cavity Not infrequently in small children knotted masses of worms produce acute obstruction of the bowel and require immediate surgical intervention Even when the worms cause little or no traumatic damage the by products of living or dead worms may produce marked toxic manifestations as edema of the face and giant urticaria, accompanied by insomnia loss of appetite and weight extreme nervousness and in extreme cases cachexia Moreover it has been convincingly demonstrated that *Ascaris* children like hookworm children are mentally retarded A moderate eosinophilia may be expected in ascariasis otherwise the blood picture is not materially altered

Diagnosis is made by the recovery of the eggs of *Ascaris lumbricoides* in human feces Usually fertile eggs will be found but where female worms alone are present only infertile eggs will be found In about 5 per cent of infections only males are present and diagnosis must be tentatively based on symptoms until a therapeutic test has been made In most infections technics for concentration of the eggs from feces are unnecessary to provide specific diagnosis due to the large number of eggs discharged daily by each female worm The spontaneous passage of one or more worms by anus or mouth does not necessarily mean that additional worms are present This can be verified by stool examination two or three days after the worms have been evacuated

Prognosis is good except in patients where obstruction or grave traumatic injury has been produced by the worms

Treatment is best accomplished by the administration of caprokol (hexylresorcinol crystoids) which has a 90–95 per cent worm removal rate for *Ascaris* Following pretreatment purgation the night before with one ounce (30 Gm) of Glauber salts dissolved in a glass of water the drug is administered in one dose in the morning on an empty stomach in hard gelatin capsules of 0 1 or 0 2 Gm size For children of pre-school age the dosage is 0 4 to 0 6 Gm (6 to 9 gr) for children from 6 to 10 years 0 8 Gm (12 gr) for older children and adults 1 0 Gm

(15 gr) The patient is required to swallow the capsules without chewing them to prevent superficial irritation of the buccal mucosa Food is proscribed for four to five hours and a post treatment purge of Glauber salts is given two hours after the drug to evacuate dead and dying worms as soon as possible and thus prevent absorption of their toxic products An alternative prescription which is valuable in combined infections of *Ascaris* with *hookworms* or *Trichocephalus* is the following tetrachlorethylene 2 7 cc (40 minims) oleum chenopodii 0.3 cc (5 minims) in 0 5 cc capsules or on a teaspoon with sugar Pretreatment Glauber salts purgation the night before administration of the anthelmintic on an empty stomach and post treatment Glauber salts purgation are indicated For children the dosage is 3 minims per year of age up to 15 years

The above prescriptions are eminently satisfactory for intestinal ascariasis During migration of *Ascaris* larvae through the lungs and for ectopic infections there is no specific chemotherapeutic procedure Physicians are requested to be *Ascaris* conscious in cases of atypical pneumonias especially in children in *Ascaris* communities

Prevention constitutes an integral part of the protection of human beings against the possible dangers of *Ascaris* infection since successful treatment of individual cases does not prevent reinfection from the same seed beds where infective stage eggs are planted Children must be taught to use sanitary toilets or privies on all occasions and must be warned of the dangers of contaminating fingers candy or play objects with soil Heavily infested ground around the house should either be treated with live steam (70° C for five minutes is lethal for *Ascaris* eggs) or spaded up and the top soil turned under Ascariasis in hogs is not a source of human infection since human and porcine strains are physiologically distinct

ERNEST CARROLL FAUST

ENTEROBIASIS

(Oxyuriasis)

Enterobiasis familiar to most clinicians as oxyuriasis is infection with the pinworm or seatworm *Enterobius vermicularis* The adult worms are small delicate objects (male 2–5 mm by 0 1–0 2 mm female 8–13 mm by 0 3–0 5 mm) and are provided with a pair of ear like lateral flaps or alae in the cervical region The male has a ventrally curved posterior end the female a sharply pointed tail

Life History—These worms live as young adults typically in the cecum and appendix with their heads attached to the mucosa Gravid females become free and migrate in the bowel usually down and out the anus especially at night when the patient retires The worms crawl in a sinuous path on the perianal and perineal skin discharging their eggs *en route* They seldom if ever return to the bowel In female patients the worms may enter the external meatus of the genital tract crawl up to the tubules and migrate into the peritoneal cavity Eggs are layed within the bowel only in about 5 per cent of positive cases and such eggs are usually nonviable Those deposited by thousands outside the anus are practically mature when deposited They are hyaline colorless ovoidal objects with a relatively thick shell usually flattened on one side measuring 50–60 by 20–30 microns and contain a coiled, frequently motile larva

They may produce infection by direct anus to mouth contamination the common method of reinfection or by being distributed by air currents from bed linen pajamas etc onto objects in the bedroom and then getting into the mouth from fingers in contact with contaminated objects Infection is commonest in children especially in large families or in institutions Enterobiasis is also common in mental hospitals The highest incidences of infection occur in large dormitory groups the lowest in families where each individual has his own bedroom The mature eggs upon being swallowed hatch in the small bowel and the emerging larvae migrate slowly down to the levels of the cecum and appendix where they become attached and develop into adults in two months or possibly less

Morbid Anatomy—Pathologic processes are at times developed at the sites where the adult worms reside especially in the tip of the appendix Considerable hemorrhage may occur at the points of attachment while pyogenic organisms invade the aban

doned sites and may initiate inflammatory reactions, at times leading to submucosal abscess formation The clinical picture is that of acute or subacute appendicitis Eosinophilia and leukocytosis may or may not be produced By and large however the principal difficulty produced in enterobiasis is associated with the migration of the gravid females out of the anus and on the perianal and perineal skin and at times causes almost insufferable pruritus This leads to scratching of the area and consequent contamination of fingers Frequently the itching skin becomes inflamed or raw and may require treatment with antiseptic ointment as yellow oxide of mercury Chronic pruritus leads to insomnia nervousness at times hysteria rarely convulsions in small children Nycturia in boys and nymphomania in adolescent girls are complicating states not infrequently observed

Diagnosis based on recovery of eggs of *Enterobius* in feces even by concentration technics is hopelessly inadequate Six or seven consecutive cellophane swab examinations (Sawitz), of the perianal and perineal skin preferably in the morning before the patient bathes or defecates provide a nearly perfect criterion of infection

Prognosis is almost always good especially with adequate treatment

Treatment consists preferably in the administration of gentian violet medicinal in the form of four hour Seal Ins or Enseals coated tablets of ⅙ or ½ grain (0 012 or 0 03 Gm) size For adults a course of treatment consists of one grain (0 06 Gm) three times daily with meals for eight days rest one week then repeat treatment For children the dose is ⅙ grain (0 01 Gm) daily for each year of apparent not actual age This treatment should be given to all infected persons in the family or other environmental group otherwise there will be repeated reinfection With mass therapy as recommended 90 per cent cures may be expected

Prevention has not been successful where only hygienic measures have been carried out On the other hand mass therapy with gentian violet has proved successful in most groups Occasional refractive cases suggest the need of temporary abandonment of the infested habitat since it is unlikely that the eggs remain viable for more than a few weeks Only by persistent efforts can eradication be effected

Ernest Carroll Faust

FILARIASIS

Filariasis is an infection with one or more of several true filaria worms which are thread like and have the following general characteristics and life cycle

Life History —The female worms in their natural habitats in the human body give birth to delicate elongate embryos known as *microfilariae* If the old egg shell remains around the microfilaria it is said to be sheathed if the microfilaria is naked it is unsheathed These microfilariae periodically or constantly migrate through peripheral blood vessels (or through cutaneous tissues) from which they are taken up by appropriate species of blood sucking flies Within the fly the microfilariae migrate from the lumen of the stomach' to the thoracic muscles where they metamorphose into sausage shaped first stage larvae These larvae grow metamorphose through several stages and in approximately two weeks or less become motile filariform larvae They now migrate down the proboscis sheath of the fly and at the time of the fly s next blood meal are introduced into or nearby the puncture wound which they make in the human skin These infective stage larvae then migrate from the skin to the sites where the adult worms will eventually mature The incubation period is usually one year or less after which the females of this new generation give birth to a brood of microfilariae

The following table (Table 1) provides information on the human filaria worms which are important either from the point of view of the pathologic changes and symptoms that they produce or from their prevalence over large areas of the world

Bancroft s Filariasis —This filarial infection is produced by *Wuchereria bancrofti* a delicate thread like worm which lives in lymph vessels and lymphoid tissues particularly in the groin and the lymphoid tissues associated with the external genitalia

Life History —Infection is initiated when

the filariform larvae are introduced onto or into the skin by infected mosquitoes especially *Culex fatigans* the tropical house mosquito Nothing is known of the subsequent history of these larvae until they mature into adult worms and the fertilized females begin discharging microfilariae This *incubation period* requires about one year and is usually symptomless This is succeeded by the *patent symptomless period* which continues for months or even years The microfilariae pass from the immediate vicinity of the parent worms into lymph vessels and thence into visceral blood vessels Typically at night (especially between midnight and 2 a m) when the patient relaxes the microfilariae surge through the peripheral circulation but return to the viscera during daytime when the patient is active

Symptoms —Sooner or later however the patient becomes toxic with frontal headache and a feeling of depression These prodromata are followed by the *acute period* with inflammation of the involved superficial lymph vessels which become raised and exquisitely painful, and an associated lymphatic fever After ten days to two weeks the lymphangitis disappears and temporarily the patient returns to a state of well being Recurrence of the inflammatory process may be anticipated usually at periodic intervals and eventually the *chronic period* gradually replaces the acute stage

Morbid Anatomy —The pathologic basis for the acute and chronic stages consists fundamentally in cellular infiltration around the locations where the adult worms are discharging appreciable amounts of toxic by products and particularly when they become moribund later die and become calcified The acute reaction is inflammatory but is gradually replaced by extensive fibrous encapsulation of the parent worms and blockage of lymph channels distal to the worms' locations Fibrosis extends along these channels until elephantiasis with nonpitting edema of the member develops or lymph varix is produced The lower extremities male genitalia and glands of the groin are

TABLE 1 —THE MORE IMPORTANT SPECIES OF TRUE FILARIAL WORMS PARASITIZING MAN

NAME	LOCATION OF ADULT WORM IN HUMAN BODY	CHARACTERISTICS OF MICROFILARIA	INSECT INTERMEDIATE HOST AND TRANSMITTERS	GEOGRAPHICAL DISTRIBUTION
Wuchereria bancrofti (Bancroft s filaria)	Lymph vessels and lymphoid tissues especially in lower trunk and in lower extremities	Sheathed typically with complete nocturnal periodicity in peripheral blood	Species of Mosquitoes especially *Culex fatigans*	Tropics and Subtropics with extensive distribution
Wuchereria malayi (Malay filaria)	Lymph vessels and lymphoid tissues especially in upper trunk and upper extremities	Sheathed with relative nocturnal periodicity in peripheral blood	Species of Mosquitoes especially *Mansonioides* and *Anopheles* spp	Central and South China Indo-China Malaya Dutch East Indies S E India
Acanthocheilonema perstans (Persistent filaria)	Body cavities	Unsheathed without apparent periodicity	Species of *Culicoides*	North Africa coastal South America from Venezuela to Argentina Dutch New Guinea
Mansonella ozzardi (Ozzard s filaria)	Body cavities	Unsheathed without apparent periodicity	Species of *Culicoides*	South America Yucatan West Indies
Onchocerca volvulus (convoluted filaria)	Subcutaneous tissues immobilized in fibrous tumors	Unsheathed migrates through skin not in blood vessels	Species of *Simulium*	Africa Pacific slope of Southern Mexico and Guatemala
Loa loa (loa worm eyeworm)	Subcutaneous tissues migrating	Sheathed with diurnal periodicity in peripheral blood	Species of *Chrysops*	Africa

most frequently involved but the processes may extend into the peritoneal cavity (with chylous ascites) or into the bladder (with chyluria) It is entirely likely that with the almost complete loss of cutaneous blood circulation in the involved member and the consequent cracking of the skin pathogenic bacteria and fungi enter and complicate the picture they may in fact be responsible for initiating recurrent acute attacks of lymphatic fever Nevertheless there is adequate evidence to support the view that the initial lesion is immediately around the adult worms and is of filarial origin

Diagnosis may be accomplished during the patent symptomless period and the acute stage by the recovery at night of the characteristic microfilariae in thick-drop blood films stained with Giemsa stain When the adult worms die the production of microfilariae ceases so that dependence must be placed on gross pathology and x ray evidence of calcified worms in the midst of the lesions Ultimate prognosis is relatively poor due to the amount of fibrous tissue repair

Treatment is not eminently successful There is no specific anthelmintic available Sulfonamides should be used for streptococcic and staphylococcic invaders Surgical procedures include radical operation to remove elephantoid tissues and a modified Kondolean operation for the lower extremity Knott (1938) has used tight Turkish towel bandaging of the involved lower extremity and has reported marked success in reestablishing drainage through collateral lymph channels reduction of the elephantoid tissues and reestablishment of blood circulation in the skin

Prevention of Bancroft s filariasis is a difficult problem It involves fundamentally the clearance of mosquito breeding sites around endemic foci but considerable protection may be temporarily afforded by screening together with the use of pyrethrum sprays and repellants such as Sta way against adult mosquitoes

Filariasis malayi is produced by *Wuchereria malayi* which is closely related to but specifically different from *W bancrofti* The development in the mosquito (*Mansonioides Anopheles* etc) method of inoculation of the human victim incubation period patent symptomless period and the development of the acute and chronic states are much the same as in Bancroft s filariasis except that the lesions occur preponderantly in the upper trunk and upper extremities *Diagnosis* is made in a similar manner The prognosis is usually much better, even without surgical intervention The *clinical aspects* of filariasis malayi have been little studied In Travancore India new infections have been greatly reduced by removing the water plants on which the larval stages of the mosquito *Mansonioides annulifera* live (Sweet and Pillai 1937)

Filaria infections due to *Acanthocheilonema perstans* and *Mansonella ozzardi* have a widespread distribution (see Table 1) but produce no proved pathology or symptoms of clinical grade It is important to recognize the diagnostic characters of their microfilariae so that infections with these worms will not be confused with pathogenic filariae of man

Onchocercosis is produced by *Onchocerca volvulus* which is transmitted by the biting gnat *Simulium* In Africa it has an extensive distribution in the Western Hemisphere its distribution is limited to a narrow strip of coffee growing uplands on the Pacific slope of Guatemala and to the States of Chiapas and Oaxaca possibly elsewhere in Mexico The adult worms live tightly coiled usually in pairs in fibrous subcutaneous tumors which become palpable within a year or less after exposure to the infection They vary in size from a pea to a small orange The tumors may be located on any part of the body In Africa they are found conspicuously at the junctions of long bones in Guatemala and Mexico most of the tumors are on the head especially in the temporal areas and occiput The unsheathed microfilariae escape from the parent tumors and migrate through the skin and subcutaneous tissues frequently accumulating in the corneal conjunctiva tissues of the eye ball or in the optic nerve The parent lesion is usually painless seldom abscesses and causes little functional damage On the other hand the invasion of the microfilariae into the tissues of the eye provokes damaging changes (including inflammation of the iris the ciliary body retina and choroid punctate hemorrhage around the limbus punc

tate vascular or interstitial keratitis of the cornea, and edema of the conjunctiva), leading to photophobia and diminished vision Involvement of the optic nerve leads to complete blindness Moreover inflammation of the tissues in the temporal area may produce an erysipelatoid appearance especially around the ear and on the ear lobes

Diagnosis of onchocercosis may be suspected in patients living in endemic areas or previously exposed there who have one or more characteristic parent tumors especially with evidence of diminished vision Specific diagnosis requires the demonstration of the microfilaria of *O volvulus* obtained from biopsied skin near the tumor or from biopsied corneal conjunctiva, or in the aspirate of the tumor after puncture

Treatment—There is no eminently satisfactory chemotherapeutic The tumors should be removed as soon as they develop to reduce the likelihood of eye damage from microfilarial invasion Plasmochin (0 1 per cent solution) when introduced into the anterior chamber of the eye is believed to arrest ocular symptoms by killing the microfilariae Prevention might be accomplished by cleaning out breeding places of the *Simulium* intermediate hosts but since these locations are usually under stones in mountain streams no practical control has been developed However relatively good results have been demonstrated in endemic foci by enucleation of the parent tumors in patients as soon as they appear

Loaiasis is produced by Loa Loa the so called eyeworm because of its propensity to wander across the front of the cornea during its continual migrations through the peripheral tissues of the body This thread like nematode lives as a mature organism in the subcutaneous tissues but is not immobilized within a fibrous tumor as is *Onchocerca volvulus* It characteristically advances a few centimeters a day in a raised serpentine track and during its wanderings typically reaches the temporal region and passes under the corneal epithelium across the front of one eye the bridge of the nose then the other eye and finally out to the other temple and down the neck to the trunk In its migrations the worm sets up a temporary inflammatory reaction referred to as a fugitive swelling' There is no permament impairment of tissues or organs only the inconvenience and nervous reaction from constant slight irritation The microfilariae are diurnal in their appearance in the peripheral blood stream They are picked up by the mango fly *Chrysops* in which they are transformed into infective stage larvae and are then inoculated again into man The disease is confined to the Continent of Africa but in the United States occasional cases are seen with a history of having lived in endemic foci

Diagnosis is frequently provided by patients who know of the migrations of the parent worms in their peripheral tissues The lesions must not be confused with those of creeping eruption (*vide supra* p 415) The characteristic sheathed microfilariae present in peripheral blood in the daytime provide specific diagnosis

Prognosis is always good

Treatment consists in the skillful extraction with a sharp hooked needle of the parent worm as it migrates under the epithelial layer of the cornea Novocaine anesthesia is not advised since it drives the worm back into inaccessible tissues

Prevention consists in avoiding water courses around which mango flies breed and hover

ERNEST CARROLL FAUST

DRACUNCULOSIS

(Dracontiasis)

Dracunculosis is produced by *Dracunculus medinensis* referred to as the dragon worm Medina worm or Guinea worm This worm superficially resembles the true *filaria* worms but in structure and life cycle is quite different The male worm is a small thread not over 40 mm in length while the female measures 70 to 120 cm in length by 0 9 to 1 7 mm in diameter

Life History—The mature worms live in the viscera or deeper somatic tissues of man and several species of mammals The gravid female migrates to the skin and on arrival produces a cutaneous blister over her anterior extremity When this area comes in contact with fresh water or a goat skin water bag seeps water onto the skin of the carrier s back the blister bursts and the

dragon worm discharges a brood of rhab ditoid larvae into the water These larvae are picked up by little water fleas of the genus *Cyclops* migrate to the hemocelic cavity of the *Cyclops* and mature When man or other susceptible host then swallow raw water containing the infected fleas he acquires the infection which requires about one year for incubation Following this the gravid female migrates to the skin to shed her progeny

Endemic Regions —This infection is highly endemic in extensive areas of India Arabia Persia Afghanistan Turkestan the southeastern states of the U S S R and Africa Autochthonous cases have been re ported from the Dutch East Indies the Guianas and Bahia (Brazil) In the United States and Canada fur bearing mammals and in China dogs may be infected but no native human cases have been reported from these latter countries

Symptoms —During the migration of gravid female dragon worms from the deeper tissues of the body to the skin there is typi cally a pronounced histamine like symptom complex which is readily amenable to epine phrine therapy The subsequent period of weeks during which the female is discharg ing larvae through the skin opening is one subject to invasion of pyogenic bacteria which constitute the greatest hazard of the infection Since time immemorial infected natives have pulled out the worm a centi meter or two a day by coiling it around a small stick which is bound to the site be tween manipulations Attempts to pull the worm out rapidly invariably causes it to break off in its tunnel with suppuration No practical modern aseptic procedure has been developed to supplant the native technic

Diagnosis is usually self made by infected patients who regard the infection as a God sent affliction

Prognosis is good except when septicemia develops

Treatment —There is no satisfactory chemotherapeusis Probably the most practi cal *control measure* consists in placing small fishes in all bodies of fresh water as ponds wells etc in endemic areas to eat the in fected *Cyclops*

The **Gordiacea** or hair worms (hair snakes) have from time to time been re ported as parasites of the digestive tract of man All cases investigated have proved to be ones of temporary parasitism due most likely to ingestion of raw water containing the immature or maturing worms which are temporarily free living following a parasitic phase in grasshoppers and other insects

ERNEST CARROLL FAUST

HOOKWORM DISEASE

(Ancylostomiasis Uncinariasis Tropical Chlorosis Miner s Anemia)

Definition —Hookworm *disease* is a clin ical syndrome caused by infection with *Ancylostoma duodenale* or *Necator americanus* Hookworm *infection* implies the harboring of hookworms in the intestine with or without symptoms

History.—*Ancylostoma duodenale* was discovered by Dubini in Italy in 1843 *Necator americanus* was discovered by Allen J Smith in Texas and by Ashford in Puerto Rico and was named by Stiles in 1902 Clinical hookworm disease was first recognized as such by Perroncito in 1880 in laborers who were constructing the Saint Gotthard tunnel through the Alps Looss in Egypt discovered that the larvae penetrate the skin and in 1904 demonstrated the route of migration of the larvae through the blood and respiratory tract to the intestines

Distribution and Incidence —Hookworm infection is endemic in many parts of the world between 36 degrees north latitude and 30 degrees south latitude Light infections are found in hot dry climates and moist cooler climates where environmental condi tions are favorable Moisture warmth, sandy or loose soil and promiscuous de-fecation are the chief factors responsible for heavy infections A mean monthly tempera ture of 50° F is necessary for the develop-ment of the larvae in the soil Regions hav ing less than forty inches of rainfall a year may show a high incidence of light infections but rarely have heavy infections The dis ease is almost entirely rural except for mines where excreta disposal is unsanitary The occupations in addition to farming and mining which are most often associated with hookworm disease are coffee tea sugar cacao and banana raising in the tropics and mulberry growing associated with the silk worm industry in China and Japan This is

because the people work barefoot in fields fertilized or contaminated with human excreta The two species of hookworms originally had separate areas of distribution, both being limited to the Old World Ancylostoma north of the 20th meridian of north latitude Necator south of this meridian The present distribution is due to the migration of people from the original areas Ancylostoma is present alone in the Mediterranean area parts of India northern China and Japan and in most mines Necator in Central and South Africa and in North and South America The two worms are found together in parts of India southern Asia and parts of Central and South America The hookworm belt in the United States is principally along the Atlantic and Gulf seaboards from North Carolina to eastern Texas The other important area is the southern Appalachian region including southwestern Virginia western North Carolina eastern Kentucky and eastern Tennessee In some tropical areas where hookworm campaigns have not been conducted practically 100 per cent of the rural population are infected Where such campaigns have been conducted and where sanitary disposal of excreta has been introduced a considerable reduction has taken place Studies by Keller and Leathers from 1930 to 1938 in six southern states showed that there had been a reduction in incidence of hookworm infection in the rural white population of these states from 39 per cent to 18 per cent since 1910–1914 when the original survey was made by the Rockefeller Sanitary Commission

The white and brown races are more susceptible than the Negro In infected families the larger the number of infected individuals the greater is the average intensity of infection Incidence and intensity increase with age up to the fifteen to nineteen age group after which there is a gradual decline Males show a higher incidence and intensity than females and the peak comes a little later in life This is undoubtedly due to greater exposure

Etiology —The human hookworms are nematodes (round worms) measuring about 1 cm in length the female being slightly larger than the male Ancylostoma is slightly larger than Necator The anterior end is curved dorsally The buccal cavity is armed with ventral teeth (Ancylostoma) or cutting plates (Necator) The male has a copulatory bursa at the posterior end consisting of finger like rays The worms inhabit the small intestine mainly the jejunum They attach themselves to villi which are sucked into the buccal cavity and they secrete toxic fluid which causes dilatation and rupture of the capillaries and prevents coagulation of the blood The worms feed mainly on blood and lymph pumped into the intestine of the worm by the muscular esophagus The worms are wasteful of this food only fluid constituents being absorbed Most of the ingested material is rapidly excreted through the anus Wells showed that a single dog hookworm could ingest 0 8 cc of blood daily if it fed continuously Although a hemolytic toxin has been demonstrated in extracts of hookworms it has not been shown that such a toxin contributes to the anemia or other symptoms The life span of the hookworm may be several years the heavier the infection the shorter the average life span of individual worms

A female hookworm lays between 6000 and 15 000 eggs per day, Ancylostoma more than Necator The larva develops rapidly in the egg and hatches under favorable conditions of moisture and temperature in about three days The rhabditiform larva ruptures the egg shell and after two moltings within a few days becomes an infective filariform larva enclosed in a transparent sheath This larva may travel upward or downward in the soil for a few inches as changes in moisture require Its life span may be several weeks in moist soil although it does not feed as long as it retains its sheath When the skin of man is exposed to infected soil the larva penetrates rapidly enters a blood vessel and is carried to the lungs where it breaks out into an alveolus It then makes its way up the bronchi and trachea into the pharynx and is swallowed and passes into the small intestine where it develops into an adult About six weeks is required from the time of penetration of the skin until eggs appear in the stools

Clinical symptoms are dependent mainly upon the chronic loss of blood producing a secondary anemia A diet low in iron content as is found among the rural people in

many parts of the world prevents recuperation from the loss of blood sometimes even after the worms have been expelled A vicious cycle consisting of poor nutrition, inability to work and poverty is established in heavy infections and contributes largely to the problem of the disease

Morbid Anatomy —The *blood* in heavily infected persons presents a chlorotic type of secondary anemia in which the average volume of the red blood cells is considerably decreased and the hemoglobin is reduced in greater proportion than the number of erythrocytes A few nucleated red cells may be found In extreme cases a picture of primary anemia may be present but this is probably due to other complicating factors The white blood cells are usually normal in number and proportion except that there is usually an eosinophilia ranging from 5 to 25 per cent The eosinophilia is more prominent in early infections and may be absent in severe cases The *bone marrow* shows an increase of cellular elements and vascularity There is an increase of young hematopoietic cells and a great increase of red cells in the normoblast stage The *spleen* is usually somewhat reduced in size The *liver* may show marked fatty infiltration The *small intestine* in patients dying of the disease usually shows some atrophy of the epithelium and increase in the connective tissue elements of the mucosa This has been interpreted as a possible explanation of the apparent inability of severe hookworm cases to absorb important food elements in normal amounts Petechial hemorrhages are found at the site of attachment of the worms The *heart* is dilated and its muscle flabby There is often edema of the tissues and sometimes even of the brain and free fluid in the serous cavities

Symptoms —*Stage of Invasion* —The larvae in penetrating the skin produce lesions which are called ground itch They consist of maculopapules which become small vesicles These are often confluent and rupture discharging serous fluid They are surrounded by local erythema and swelling Itching is severe The commonest site is on the feet particularly between the toes but in miners may be on the arms legs or buttocks Regional lymph nodes are often enlarged especially if secondary infection takes place

The larvae in passing through the lungs may produce bronchitis if a heavy infection occurs at one time It may be accompanied by fever It has been noted particularly among miners

Symptoms Produced by Adult Worms —Very light infections usually produce no recognized symptoms but elimination of the worms sometimes increases the vigor or accelerates normal development in children Mild cases show slight pallor of the skin with a yellow tinge dryness of the skin with decreased perspiration sometimes slight discomfort in the abdomen slight palpitation of the heart on exertion slight weakness of the muscles and distaste for work The appetite may be increased Bowel movements are usually normal Such cases usually show 4 000 000 to 5 000 000 red blood cells per cubic millimeter hemoglobin between 60 and 80 per cent, and slight or marked eosinophilia

Moderately severe cases show an exaggeration of the above symptoms The hair is dry and lusterless the expression of the face is dull there may be general itching of the skin the appetite may be voracious and the eating of earth or other mineral material may be indulged in although it is rarely admitted The tongue shares in the general pallor and may show atrophy of the papillae The bowels are usually constipated but there may be irregular intervals of diarrhea The heart shows slight hypertrophy the pulse is rapid and often weak and a hemic systolic murmur is usually heard over the precordium There is usually dyspnea on exertion There may be dizziness tinnitus and headache Weakness is marked fatigue is rapid and movements are slow There may be a slight amount of albumin in the urine with or without a few casts There may be edema of the feet The blood picture shows from 3 000 000 to 4 000 000 red blood cells per cubic millimeter The hemoglobin is between 30 and 60 per cent and eosinophilia is usually present

Severe cases show further intensification of the anemia and cardiac dilation Weakness and stupor are apparent Edema may involve the entire body including the face and the serous cavities and cardiac insufficiency may be present Slight exertion causes severe dyspnea The reflexes may be

abolished and paresthesias are present The skin is very dry The appetite may be enormous or poor The stomach may become dilated and nausea and vomiting are frequent Diarrhea may predominate over constipation The *stools do not contain gross* blood but occult blood is readily found The urine may show more albumin and casts These patients show between 2 000 000 and 3,000 000 red blood cells and 10 to 30 per cent of hemoglobin The color index sometimes exceeds 1 Eosinophilia is usually absent

In addition to the above symptoms hookworm disease retards general development Puberty is often delayed and if it occurred before infection took place sexual development may recede The age of the patient may appear five to ten years younger than it actually is Mental development is proportionately retarded In adults impotence may occur in men and menstruation cease in women

Diagnosis —The final diagnosis of hookworm infection is based entirely upon the demonstration of ova in the stools The simplest method is by a slide cover slip preparation of an emulsion of stool in water or saline A rough estimate of the intensity of infection may be gained from such a preparation but very light infections may be missed The salt flotation method in which an emulsion of about 1 cc of feces is made in 10 cc of a saturated solution of sodium chloride and allowed to stand for half an hour brings the eggs to the surface and permits the finding of very light infections Various methods have been developed for estimating the number of worms in the intestine and these are valuable in surveys of population groups in order to determine the clinical importance of the disease in such groups These methods however are not necessary in clinical practice since all persons harboring hookworms no matter how few in number should be treated for their removal The most important element in diagnosis is to keep the disease in mind in the presence of symptoms and to examine routinely the feces of every patient in areas where the disease might be present

Prognosis —Unless the patient is in the last stages of the clinical disease elimination of the worms should be followed by ultimate cure in the absence of reinfection Even the most severe cases may show dramatic improvement when the worms are eliminated and iron is administered Studies by Rhoads Castle and their associates have shown *however that in Puerto Rico* at least, chronic cases in which the anemia is pronounced do not improve rapidly after removal of the worms unless iron is given in large doses and that almost the same improvement in the blood picture can be obtained by the administration of iron without removal of the worms This emphasizes the importance of stimulating blood formation in hastening recovery from the disease

Treatment —A number of drugs have been advocated for the elimination of hookworms The chief problem has been to obtain a drug which is toxic for the worms but not toxic for the patient

Thymol finely particulated and mixed with an equal part of powdered lactose or sucrose in capsules and administered in a single dose of 4 Gm will remove about 50 per cent of the worms in one treatment The dose for children is 0 3 Gm per year of age up to twenty A few deaths following thymol have been reported but most of these were avoidable

Oil of chenopodium in three doses of 0.5 cc each in hard gelatin capsules at intervals of one half hour removes 70 to 90 per cent of the worms Children may be given 0 03 cc per year of age up to age fifteen A considerable number of deaths from this drug have been reported apparently due to idiosyncrasy or to excessive absorption

Hexylresorcinol in crystalline form in specially prepared hard gelatin capsules will remove 50 to 60 per cent of hookworms The adult dose is 1 Gm The dose for children is 0 1 Gm for each year of age up to age ten The advantage of this drug is that it is entirely nontoxic The crystals however will burn the mouth if the capsules are crushed and the drug combines quickly with organic matter so that food must be strictly avoided for twelve hours before and four hours after treatment

Tetrachlorethylene is probably the drug of choice because of its efficiency and lack of fatal toxicity No deaths have been reported Dizziness sometimes occurs The dose is 3 cc in hard gelatin capsules or in

skimmed milk given at one time Children may be given 0 2 cc for each year of age up to age fifteen This treatment will remove from 60 to 80 per cent of the worms If a heavy Ascaris infection is present with the hookworms Ascaris should be removed by hexylresorcinol before treatment for hook worms is given because tetrachlorethylene only stimulates Ascaris to activity and a large number of these worms might produce intestinal obstruction

Carbon tetrachloride should not be used as an anthelmintic because it may cause fatally toxic necrosis of the liver and is but little more effective than tetrachlorethylene

The toxic symptoms of thymol and oil of chenopodium usually appear from two to twenty four hours after treatment They are in general the same for the two drugs and consist of nausea vomiting dizziness stupor and coma They should be treated as early as possible by purging preferably with sodium sulfate and by general supportive measures

Preparation for anthelmintic treatment is important but can be overdone The patient should have a light evening meal without fats and should receive the drug in the morning before breakfast A preliminary purge is not necessary unless constipation is present Food should be omitted for a few hours and alcohol for twenty four hours after treatment A purge is usually advisable four hours after treatment in order to elim inate the worms and the drug Sodium sulfate is preferable to magnesium sulfate because the latter sometimes acts as a de pressant

Since one treatment with an anthelmintic rarely removes all of the worms the stools should be carefully examined for eggs five or six days after treatment and if they are found the treatment should be repeated at weekly intervals until the stools become negative

Iron should be given in large amounts The recommended daily dosage is 1 Gm of ferrous sulfate (exsiccated) in capsules or 6 Gm of ferric ammonium citrate in a 50 per cent solution These preparations should be given in three divided doses after meals It is best to start with smaller doses in order to avoid intolerance Children should receive doses in proportion to their weight This treatment produces rapid stimulation of reticulocytes and increase of hemoglobin and red blood cells with rapid general im provement of the patient. Liver extract is of no value except for its iron content The diet should be abundant and well balanced but this alone will not cause rapid improve ment unless it has a very high iron content

Prophylaxis —There are three important elements in prevention treatment the wear ing of shoes and sanitary disposal of ex creta Treatment is only of temporary value if reinfection can take place The wearing of shoes is dependent upon local customs and education The only effective method of prevention is sanitary disposal of excreta This must be adapted to the individual and community involved Since the larvae can not climb up a vertical surface to any height the deposition of excreta anywhere except on the ground is sufficient for prevention The bored hole latrine in many parts of the tropics and the pit privy in the rural por tions of the United States are sufficient to insure prevention if they are properly used Hookworm is still an important public health and clinical problem in many parts of the world including certain areas in the United States and will continue to be until sanitary disposal of excreta becomes uni versal

HIRUDINEA

HIRUDINIASIS

(*Leech Infestation*)

HIRUDINIASIS is leech infestation Leeches are related to the earth worms They are segmented elongated oval objects usually concave on the ventral side and convex dorsally and possess two suckers one around the mouth and a blind one posteriorly They live primarily in water or in moist tropical environments Many leeches suck blood as a source of food They secrete *hirudin* an anticoagulin to prevent the blood from clotting after they have ingested it Their digestive tract is provided with numerous lateral diverticula capable of tremendous distention when the leech is engorging itself with blood

For centuries leeches have been used to let blood from patients While their previous utilization has been indiscriminate and usually ill advised there is probably justification for their application in certain types of essential hypertension and locally in certain cases of thrombosis and varicose veins For this purpose the cultivated medicinal leech *Hirudo medicinalis* is customarily employed

Injury Inflicted —Leeches are injurious to man in two ways externally and internally

External hirudiniasis is due to several species of land leeches which commonly live in tropical rain forests as in Ceylon Borneo the Dutch East Indies Australia Madagascar the lower valleys of the Himalayas and the northern Chilean Andes When man passes through such areas the leeches attach themselves to his skin even gaining entrance through heavy khaki pants and leather boots For the moment they cause practically no pain and are usually not noticed until the infested area of the body begins to ooze blood The wounds remain open for weeks become readily infected with pyogenic bacteria and heal with difficulty Occasionally profound exsanguination from multiple abandoned sites causes the death of the victim

REMOVAL OF LEECH —No attempt should be made to use force in pulling off a feeding leech lest the animal s jaws be left in the wound A few drops of brine or strong vinegar or a match flame applied to the worm will cause it to relax when it may be easily removed The wound should then be washed with a mild antiseptic solution, such as boracic acid staunched if necessary with a styptic pencil treated with calamine lotion and covered with an aseptic dressing

Internal hirudiniasis is most commonly caused by accidentally taking into the mouth in raw drinking water small leeches which become attached to the buccal mucosa epiglottis pharynx upper level of the esophagus naso pharynx larynx vocal cords trachea or even a bronchus The most notorious species of leech involved is *Limnatis nilotica* which lives in quiet brooks streams ponds and lakes in southern Europe northern Africa and the Near East while related species are found in west or central Africa and Malaya They may cause only moderate swelling of the area to which they become attached on the other hand they may produce painful or dangerous obstruction of passages with epistaxis hemoptysis or hematemesis at times leading to exsanguination, continuous coughing with slimy bloody discharge hoarseness or complete loss of speech pain in the nasal passage throat or chest dyspnea with or without cyanosis difficulty in swallowing and nausea suffocation at times leading to death Likewise persons wading or bathing in infected water may suffer infestation of the urethra urinary bladder or vagina

REMOVAL OF LEECH —If the leech is lodged in the upper respiratory passages it may be cocainized after it has been visualized then removed by gentle traction with an appropriate pair of forceps If the leech is in the posterior pharynx larynx trachea or bronchi the patient is placed in a Trendelenburg position the worm visualized through a bronchoscope cocainized and removed with greatest care The patient must be warned against taking a deep breath lest the leech be more deeply drawn into the respiratory tract Rarely tracheotomy is required to save the patient s life

On the other hand if the leech is lodged below the epiglottis in the upper level of the esophagus no fear may be experienced if it should be swallowed since it will be digested in the stomach For urogenital infestation strong saline irrigation is advised

PREVENTION —Care must be taken to filter or at least strain all water in infested areas before it is drunk

ARTHROPODS AND HUMAN DISEASE

ARTHROPODS (Phylum ARTHROPODA) comprise the insects and their allies and constitute the largest assemblage of species in the Animal Kingdom Moreover many of the species exist in almost uncountable numbers While some of the arthropods are among man s best friends for the most part they are economically and medically harmful Members of this phylum are many celled invertebrates which are segmented along a longitudinal axis They possess a small body cavity and a large hemocelic cavity which penetrates into practically all the parts of the animal and is filled with the blood fluid They have a chitinous exoskeleton Most species have a tracheate respiratory system which penetrates to all the tissues of the body and obviates an intermediate lung for the exchange of oxygen and carbon dioxide As the phylum name implies arthropods have articulated appendages typically one pair for each body segment Each appendage is primitively made up of a basal portion and an inner and outer ramus but it is usually modified for purposes of walking swimming for sensory uses (i e antennae) for apprehending and crushing prey (i e chelae maxillae and mandibles) or for protection against enemies (i e venom apparatus at the anterior or posterior end of the body) The life cycle of an arthropod may be very simple or it may be very complex The main class groups of the arthropods of medical importance are as follows (I) The CRUSTACEA which have a fused cephalothorax and two pairs of antennae They comprise smaller forms (Entomostraca) including *Cyclops* and *Diaptomus* and larger forms (Malacostraca) including the crabs crayfishes and lobsters (II) The CHILOPODA or centipedes with several pairs of similar legs (III) The ARACHNIDA including the scorpions spiders ticks and mites with four pairs of walking appendages (IV) The INSECTA including lice bugs

beetles, bees wasps and ants moths and butterflies flies and fleas, all of which have three pairs of thoracic legs

Arthropods are medically important in three capacities (1) As causative agents of disease (2) as mechanical carriers of pathogenic micro organisms and (3) as necessary hosts (or incubators) and transmitters of pathogens to man In the first category are all of the blood sucking species those which venenate and those which actually parasitize the human body In the second group are those species especially flies which come in contact with disease producing organisms through their filthy feeding and breeding habits and then pass on the pathogens to man In the third group are the obligatory arthropod hosts of such agents of disease as the malaria parasites the filaria worms the rickettsias the relapsing fever spirochetes plague bacilli and others

Ernest Carroll Faust

ARTHROPODS AS CAUSATIVE AGENTS OF DISEASE

All blood sucking arthropods, *i e* ticks many species of mites lice blood sucking bugs, blood sucking flies and fleas puncture the skin and introduce minute amounts of saliva into the puncture wound before taking a blood meal If the puncture wound is small as in the case of mosquitoes and other blood sucking gnats the trauma is slight but the protein in the introduced saliva may lead to allergic reactions with local or generalized edema and inflammation accompanied by fever In the case of ticks the wound is moderately large and may become ragged if attempts are made to remove the tick with its mouthparts unrelaxed Moreover red mites (chiggers) usually bury their heads in the skin of their victim so that removal is difficult The sarcoptic mite (*Sarcoptes scabiei*) actually tunnels in the skin and multiplies there and the follicular mite (*Demodex folliculorum*) utilizes the hair follicles for similar purposes The female chigoe (*Tunga penetrans*) burrows into the skin to secure food for the development of her eggs

The **sarcoptic or itch mite** is widely prevalent in charity clinics and in groups of the population with low personal hygiene The disease is known as *sarcoptic mange* The female which measures 330–450 microns in length by 150–200 microns in breadth has a slightly projecting head (*capitulum*) and four pairs of short conical legs She burrows into the skin *via* hair follicles and develops a somewhat tortuous tunnel several millimeters to a few centimeters in length and nearly parallel to the skin surface At the inner end of the tunnel she lays about forty ovoidal eggs over a period of four to five weeks Within three to five days after oviposition a six legged larva hatches from each egg The larvae develop lateral burrows or come out of the tunnel and produce new burrows Four to ten days later they have moulted and have become sexually mature New sites of infestation develop in this way in the skin of the same individual, or from his clothing or bed linen infest his associates

The *lesions* develop rapidly as raised red linear channels in the epidermis and are most common between the fingers on the backs of the hands elbows axillae groin breasts umbilicus penis shoulder blades and the small of the back Deposition of little fecal pellets by the mites in their burrows produces vesiculation with itching which is intensified by warmth and moisture Scratching produces an open weeping lesion which frequently becomes infected with pyogenic bacteria

Diagnosis is based technically on the recovery of the mites from the inner ends of the tunnels but the lesions are so characteristic that clinical diagnosis is relatively satisfactory

Prognosis is good with persistent treatment

Treatment—Sulfur ointment (5 per cent flowers of sulfur in lanolin) is commonly used but the more complicated Danish treatment is preferred by some physicians After all suspected lesions have been scrubbed with green soap and soaked in warm water the ointment is rubbed in before the patient retires The next day fresh clothing is put on and all soiled clothing and bed linen are sterilized by boiling This is repeated the second night and at least once again between the sixth and tenth nights to kill larvae freshly hatched from eggs For individuals sensitive to sulfur pyrethrum

ointment (0 75 per cent pyrethrins one part lanolin 2 parts and vaseline one part) or 2 per cent rotenone in vaseline may be substituted

Graham (1943) recommends a single painting of the entire skin from neck to soles of scabies infested patients following a hot bath with a 20 per cent emulsion of benzyl benzoate the effective principle in balsam of Peru He claims about 99 per cent cures disregards the possibility of reinfestation from fomites and states that the procedure is highly practical for military and civilian cases

Pediculosis is louse infestation and may refer to head lice (pediculosis capitis), body lice (pediculosis corporis) or pubic lice (pediculosis pubis) Head lice (*Pediculus humanus var capitis*) infest the head and attach their eggs near the base of the hair shafts body lice (*P humanus var corporis*) feed on the skin but usually attach their eggs to the fibers of body clothing pubic lice (*Phthirus pubis*) live closely appressed to the skin usually in areas of the pubic axillary and breast hairs occasionally in the eyebrows and eyelashes attaching their eggs to these hairs They all produce an irritating roseate papular dermatitis

Treatment —For *head lice* the hair should be cut short and the head skin thoroughly rubbed with crude petroleum and olive oil half and half then after several hours cleaned out with soap and water and the eggs combed out with a fine toothed comb For *body lice* any organisms feeding on the skin should be removed with forceps the body hairs should be shaved off and the lesions treated with 1 per cent thymol in alcohol to relieve the pruritus All clothing and bed linen mattresses etc should be sterilized by dry or steam heat fumes of methyl bromide in a closed container or dry cleaning processes For *pubic lice* crude petroleum and olive oil half and half or 10 per cent thymol in olive oil should be thoroughly rubbed into the infested areas except that in infestation of the eyelashes these antiseptics are too strong and individual lice and eggs must be removed with forceps

Bites.—For *treatment of dermatitis* due to bites of flies fleas mites and others application locally of phenolated camphor in pure mineral oil ('Campho phenique) is a satisfactory well tolerated palliative which will usually prevent sepsis

Myiasis —The largest group of tissue invaders among the arthropods is that of fly larvae (*i e* maggots) producing myiasis The mother fly may lay eggs on food or in drink which is accidentally taken into the digestive tract and produces temporary *intestinal myiasis* or may by design deposit eggs or young maggots in or nearby a wound or on the unbroken skin The maggots hatching from eggs or those already hatched invade the whole or damaged skin or mucous membranes and cause *cutaneous ophthalmic rhinal aural* or *urethral myiasis* Many of these infestations are nonspecific or only semi specific as in the case of house flies green bottles blue bottles stable flies and some species of flesh flies On the other hand specific infestation is intentional as in the case of the primary screwworm fly (*Cochliomyia hominivorax*) the sheep bots (*Oestrus ovis*) the cattle bots (*Hypoderma bovis* and *H lineatum*) the horse bots (*Gasterophilus* spp) and the tropical warble fly (*Dermatobia hominis*) Some of the semi specific and all of the specific myiasis producing flies frequently cause permanent disfigurement of the invaded skin and underlying tissues and may be responsible for death of the victim especially in case of small children Moreover wounds infected secondarily with pyogenic bacteria are much more difficult to handle than uncomplicated ones *Surgical removal* of these maggots should be accomplished as soon as diagnosis has been made

The **venenating arthropods** include centipedes scorpions spiders some ticks bees, wasps and ants blister beetles and the caterpillars of several moths

Centipedes have a pair of hollow oral fangs which are provided with basal poison glands through which venom is introduced into the victim when the fangs penetrate the skin This produces local and at times general inflammation but probably never has a fatal termination

True scorpions have a single curved hollow caudal fang through which the venom elaborated in a pair of basal glands is emptied into the skin This venom contains neurotoxins hemolysins and endothelio-

lysins In many warm countries, including the southwestern United States species of *scorpions frequently* venenate human beings whose skin accidentally contacts the scorpion as the unprotected surface of the foot or arm In Durango State, Mexico, in Trinidad, and in parts of India and Africa death especially in small children is not uncommon as a result of scorpion sting with ascending motor paralysis at times accompanied by acute pancreatitis Specific antivenins can be prepared but are not generally available Insulin has been recommend to combat the pancreatitis Caution should be exercised to prevent direct skin contact with these creatures

Spiders—All spiders are venomous but only a few species are able to penetrate human skin with their pair of oral fangs" through which the venom is discharged The most notorious spider is the 'black widow" (*Latrodectus mactans*), which has a wide distribution from Canada to Chile Its venom is a toxalbumin containing fractions which produce both an ascending motor paralysis and destruction of peripheral nerve endings There is sharp pain swelling and reddening at the site of the 'bite' dizziness and weakness, tremor of the legs and abdominal cramps after lymphatic absorption of the venom Board like rigidity and spasm of the abdominal muscles may simulate an acute appendix or tetanus More advanced symptoms include urinary retention reduced heart beat and feeble pulse labored breathing and speech light stupor convulsions in small children and delirium

TREATMENT—With a history of black widow spider 'bite" (*arachnidism*) the patient should be placed in bed given 10 cc of a 10 per cent solution of calcium gluconate intravenonusly to reduce pain and to protect peripheral nerve endings and then given immune serum (Antivenin *Latrodectus Mactans* Mulford s) Care must be exercised not to disturb black widow or other dangerous spiders lurking in their webs in caves, under rocks around the base of posts or lumber piles or on the under side of the seats of outdoor privies

Ticks—The Rocky Mountain wood tick (*Dermacentor andersoni*) and some other species of hard bodied ticks introduce a poison into the skin along with their saliva, causing an ascending motor paralysis This has been experimentally demonstrated not to be a neurotoxic virus It is most concentrated in adult females which have not previously fed and most dangerous when the tick bites at the base of the medulla No specific relief has been developed Abbott has recently provided a comprehensive review of the epidemiology and clinical aspects of tick paralysis

Bees and *wasps* have a posterior sting apparatus the modified ovipositor through which venom is introduced into human skin The venom consists of acid and alkaline fractions and a histamine like fraction Honey bees deposit the entire sting apparatus in the wound For most persons the wound is painful and may produce mild systemic reaction Some sensitized individuals die as a result of repeated stinging unless treated with epinephrine They should then be desensitized with whole bee venom made up in Coca s solution *Blister beetles* contain a vesicant which produces blisters when the coxal or body fluid of the beetle is discharged on the skin Mild applications as damp baking soda should be applied topically Many types of *moth larvae* (*i e* caterpillars) possess hollow poison hairs, at times concealed by tufts of nonpoisonous hairs In contact with human skin the poison hairs discharge minute amounts of an urticating substance which behaves like a chemical burn and heals with difficulty Palliative treatment consists in the application of calamine lotion

ERNEST CARROLL FAUST

ARTHROPODS AS MECHANICAL CARRIERS OR ESSENTIAL HOSTS

As Mechanical Carriers of Pathogenic Micro organisms—Due to their filthy feeding and breeding habits many of the common flies are able to serve as mechanical vectors of several pathogenic organisms affecting man These flies (common house fly lesser house fly biting and non biting stable flies green bottles blue bottles, blow flies flesh flies fruit flies etc) commonly feed on garbage and the dung of man and domestic animals Usually they oviposit or larviposit on such decaying organic material

and the larvae (i e maggots) feed and grow in these media After a pupal stage during which the apparently resting organism undergoes a profound internal reorganization, the adult fly emerges from the pupal case privy or other deposit of human feces and the fly next alights on human food or utensils in the kitchen or on the dining table not only are pathogenic micro-organisms likely to be transferred in vomit drops or

TABLE 1 —THE ROLE OF ARTHROPODS IN THE TRANSMISSION OF IMPORTANT DISEASES TO MAN

DISEASE	ETIOLOGIC AGENT	ARTHROPOD TRANSMITTERS	ETIOLOGIC AGENT IN THE ARTHROPOD S BODY
Yellow Fever	Unnamed filtrable virus	Mosquitoes especially *Aedes aegypti*	Multiplication (proboscis inoculation)
Dengue	Unnamed filtrable virus	*Aedes aegypti* *A albopictus*	Multiplication (proboscis inoculation)
Equine Encephalomyelitis	Unnamed filtrable virus	Mosquitoes (*Aedes* spp)	Multiplication (proboscis inoculation)
Pappataci Fever	Unnamed filtrable virus	Sand flies (*Phlebotomus papatasii*)	Multiplication (proboscis inoculation)
Oroya Fever	*Bartonella bacilliformis*	Sand flies (*P peruensis* *P noguchii*)	Multiplication (proboscis inoculation (?))
Typhus Fever Epidemic (Classical)	*Rickettsia prowazeki*	Louse (*Pediculus humanus*)	Multiplication in epithelial cells of gut wall (inoculation from bite feces or crushing on skin)
Endemic (Murine)	*Rickettsia prowazeki*	Rat flea (*Xenopsylla cheopis*)	Multiplication in epithelial cells of gut wall (inoculation from bite)
Tick Typhus (Rocky Mt and related fevers)	*Rickettsia rickettsi*	Hard bodied ticks (*Dermacentor andersoni et al*)	Multiplication in epithelial cells of gut wall (hypostome inoculation)
Japanese River Fever	*Rickettsia orientalis*	Red mites (*Trombicula* spp)	Multiplication in body (hypostome inoculation)
Relapsing Fever Epidemic	*Borrelia recurrentis*	Louse (*Pediculus humanus*)	Multiplication in tissues outside gut wall (inoculation from crushing lice on skin or from bite of tick)
Endemic	*Borrelia duttoni*	Soft bodied ticks (*Ornithodoros* spp)	
Plague	*Pasteurella pestis*	Rodent fleas especially *Xenopsylla cheopis*	Multiplication in gut (proboscis infection)
Malaria	*Plasmodium vivax* *P malariae* *P falciparum* *P ovale*	Mosquitoes (many species of *Anopheles*)	Sporogony (saliva infective proboscis inoculation)
Kala azar	*Leishmania donovani*	Sand flies (*Phlebotomus* spp)	Metacyclic development (saliva infective proboscis inoculation)
Cutaneous leishmaniasis	*Leishmania tropica*	Sand flies (*Phlebotomus* spp)	Metacyclic development (saliva infective proboscis inoculation)
Muco-cutaneous leishmaniasis	*Leishmania braziliensis*	Sand flies (*Phlebotomus* spp)	Metacyclic development (saliva infective proboscis inoculation)
African trypanosomiasis	*Trypanosoma gambiense*	Tsetse flies (*Glossina palpalis*)	Metacyclic development (saliva infective proboscis inoculation)
	Trypanosoma rhodesiense	Tsetse flies (*Glossina morsitans*)	
Chagas Disease	*Trypanosoma cruzi*	Cone-nosed bug	Metacyclic development (feces infective when rubbed into skin)
Filariasis Bancrofti s	*Wuchereria bancrofti*	Mosquitoes (especially *Culex fatigans*)	Larval development without multiplication escape from tip of proboscis sheath onto human skin
Onchocercosis	*Onchocerca volvulus*	*Simulium* spp	
Loaiasis	*Loa loa*	*Chrysops* spp	

dries its wings and flies about to take food It feeds on dissolved and finely particulate material which it sucks up into its proboscis After ravenously feeding it defecates and vomits If the feeding ground is an open fecal pellets to food drink or containers but moist feces temporarily lodged on the outside of the fly s body (i e proboscis trunk and legs) may be a source of contamination

lysins In many warm countries, including the southwestern United States species of scorpions frequently venenate human beings whose skin accidentally contacts the scorpion as the unprotected surface of the foot or arm In Durango State Mexico in Trinidad, and in parts of India and Africa death especially in small children, is not uncommon as a result of scorpion sting with ascending motor paralysis at times accompanied by acute pancreatitis Specific antivenins can be prepared but are not generally available Insulin has been recommend to combat the pancreatitis Caution should be exercised to prevent direct skin contact with these creatures

dries its wings and flies about to take food. It feeds on dissolved and finely particulate material which it sucks up into its proboscis. After ravenously feeding it defecates and vomits. If the feeding ground is an open fecal pellets to food drink or containers but moist feces temporarily lodged on the outside of the fly's body (i.e. proboscis trunk and legs) may be a source of contamination.

Role in Epidemics—Substantial proof has been furnished that filth flies have been responsible for epidemics of several enteric diseases including typhoid fever, bacillary dysentery, cholera, and amebic enteritis Moreover, suspicion has recently been again directed to filth flies in the transmission of infantile paralysis and it is epidemiologically possible that trachoma may be mechanically contracted from flies which breed in profusion in regions like India and Egypt Biting stable flies contaminated with horse manure, may introduce tetanus and anthrax spores into the skin Eye gnats (*Hippelates* spp) have been incriminated in epidemics of acute conjunctivitis ('pink eye') and are potential vectors of the spirochete of yaws

Control of epidemics of several of the above mentioned diseases at times depends primarily on *control* of *fly breeding* Homes should be adequately screened garbage cans should be tightly covered, the garbage collected daily and completely incinerated, outdoor privies should be soundly constructed should be screened and the pit kept clean with generous frequent applications of quick lime or crude oil Barnyard manure should be adequately treated and drained to prevent the breeding of stable flies In cities where screening and sanitary disposal of garbage are carried out the dangers of fly convection of pathogenic micro organisms have been greatly reduced But in rural areas particularly on large farms flies are still a menace to human health

While flies constitute the greatest danger with respect to the mechanical transmission of disease bedbugs mosquitoes and other blood sucking arthropods have been found experimentally to be suitable mechanical carriers of *Pasteurella tularensis* and the virus of yellow fever

As Essential Hosts (or Incubators) of Pathogenic Micro organisms—The disease entities for which arthropods play an essential role in development or multiplication and transmission to man are considered in other chapters of this book Hence it is desirable to call attention here only to the relation of arthropods to these etiologic agents This can be most concisely presented in tabular form (Table 1)

In conclusion it may be stated that arthropods constitute a most important part in the causation of human diseases including many endemic infections, but particularly certain epidemic diseases for which certain arthropods are the necessary transmitters Intelligent recognition of these facts by the physician will assist materially in the control of many of these diseases

DISEASES OF DOUBTFUL OR UNKNOWN ORIGIN

RHEUMATIC FEVER

(Acute Rheumatic Fever Acute Articular Rheumatism Acute Rheumatism Polyarthritis Rheumatica)

Definition —Rheumatic fever is a disease infectious in nature closely associated with invasion of the body by Group A hemolytic streptococci; it is characterized by febrile and toxic states by the presence in various parts of the cardiovascular system and joints of multiple disseminated focal inflammatory lesions and at times by serofibrinous inflammation of some of the great mesothelial lined body cavities and joints it is further characterized by a tendency for the febrile toxic and arthritic signs to disappear following the exhibition of certain antipyretic drugs in sufficient doses

Incidence.—Neither rheumatic fever nor rheumatic heart disease are reportable hence the incidence must be estimated indirectly Heart disease is among the first three causes of death in the first four decades of life in New York State There are probably between 30 000 and 60 000 deaths from rheumatic heart disease per year in the United States and at an estimated rate of 1500 to 2000 new cases per million population there would be between 200 000 and 260 000 cases of rheumatic fever per year There is considerable evidence of a falling incidence and death rate from decade to decade

Morbid Anatomy —The typical pathologic unit is a submiliary granuloma variation in location size and stage of development of these granulomata account for most of the pathologic pictures According to Klinge the earliest evidence of injury is a fibrinoid swelling of the ground substance of the connective tissue This swollen ground substance stains like fibrin Usually the collagen fibers remain intact but not infrequently small areas of fragmented fibrils are seen In this early period wandering granulocytes are encountered In from ten to fourteen days these areas are surrounded by the characteristic rheumatic granuloma cells These have basophilic cytoplasm, large vesicular nuclei frequently multiple often containing masses of dense staining chromatin McEwen showed that they probably arise from undifferentiated mesenchymal elements of connective tissue Granulocytes may persist and a few lymphocytes and plasma cells appear usually the granuloma cells gradually elongate and assume the appearance of fibroblasts until finally a scar is formed

The myocardial Aschoff body is the most typical rheumatic granuloma comparable lesions elsewhere are modified by the structure of the tissue involved Thus subcutaneous nodules are probably conglomerations of submiliary granulomata occurring in structures capable of responding more vigorously to local tissue injury than is the myocardium Similar submiliary foci are seen in the periarticular tissues and synovial membranes but there is in addition a marked increase in viscid synovial fluid containing fibrin clasmatocytes and wandering cells and the periarticular tissues are diffusely edematous Under the influence of certain antipyretic drugs the exudative components quickly disappear but the proliferative phenomena are more persistent

In rheumatic pericarditis and pleurisy the exudate is serofibrinous in the former the fibrinous characteristics may be very marked and the normal endothelial covering may be entirely destroyed and eventually replaced by organization of the exudate into fibrous tissue with partial or complete obliteration of the pericardial cavity In pleurisy less fibrin is encountered and adhesions even though present are less extensive

Rheumatic valvulitis ordinarily called endocarditis is more clearly understood if considered from the viewpoint already advanced In the gross there is a deposit of small grayish pink verrucae along the surfaces of the valves at the lines of contact of opposing cusps together with thickening of the valves Microscopically the vegetations

consist of fibrin enmeshing various cellular blood elements deposited on a portion of the valve from which the endothelium has been denuded In the substance of recently involved valves as yet practically free of verrucae there are at times areas closely resembling Aschoff bodies Small foci of proliferative inflammation with rapid vascularization are usually seen Probably the primary process is in the region of the valve rings from which an interstitial inflammation extends into the cusps, and the throm

hearts These lesions were often demonstrable only by careful microscopic examination Healing is effected by vascularization of the verrucae and by scar formation in both the valve and vegetation the endothelium at the bases of the verrucae grows over the surface and a thickened scarred less flexible valve is the usual result This valve moreover is a *locus minoris resistentiae* possibly due to its vascularity, or to the fact that the mobile scars being composed chiefly of collagen, are tissues particularly

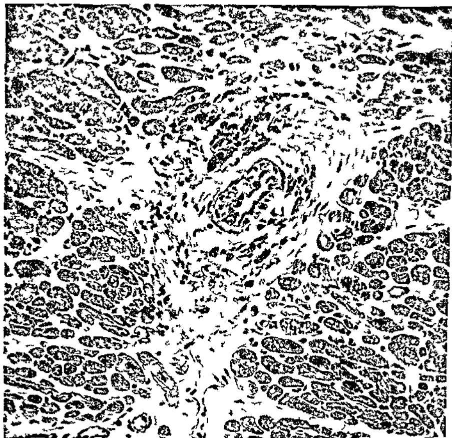

Fig 59—Perivascular granulomata (Aschoff bodies) in heart of patient with chronic myocarditis and valvulitis Note also endovascular lesions Eosin and methylene blue stain

botic verrucae appear to be secondary in nature, their localization is apparently due to mechanical trauma which causes the valvular endothelium already swollen and proliferated as a result of the underlying inflammation to be destroyed at the points of most violent impact with opposing cusps Indeed Holsti has shown that interstitial valvulitis is present in the majority of valves of the left side of the hearts of patients dying from rheumatic carditis and in about one half of the valves of the right side of the

liable to attack by the 'rheumatic poison Thus the valves of a patient who has suffered from 2 or more attacks of rheumatic fever show evidence of the previous attacks in scar formation and increased vascularity and of the last attack in new focal proliferative lesions and recent vegetations

Rheumatic granulomata not infrequently occur under and in the mural endocardium especially in the left auricle as first observed by MacCallum Pappenheimer and von Glahn and many others have described

them in the aortic adventitia with small focal scars in the media and collections of granuloma cells about the vasa vasorum In many visceral blood vessels inflammatory lesions have been seen The endothelium is swollen and separated from the wall by fibrin which may invade the entire vessel wall and be mixed with cellular debris and fragmented elastica Surrounding the vessel there may be hemorrhage exudate and typical cells very comparable to that seen in auricular endocarditis Holsti states that arteritis verrucosa is most frequently encountered in the peritonsillar and intestinal blood vessels of rheumatic subjects This lesion consists of fingerlike projections from the vessel wall into the lumen these projections are covered with elastica continuous with that from the arteries Gray and Aitken describe eccentric fibrous thickenings of small veins It thus is obvious that the poison active in this disease may affect most portions of the cardiovascular tree

In chorea minor which is probably a rheumatic affection of the brain there are disseminated focal endo and perivascular lesions and at times zones of focal encephalitis also some neuroglial increase While apparently having little similarity to cardiac granulomata it must be recalled that outside the blood vessels the brain has relatively little mesenchymal tissue hence can not respond histopathologically like other parts of the body

Etiology — *Predisposing* — Rheumatic fever is especially prevalent in the temperate zones less in the subtropics is rarely seen in the West Indies but lately has been frequently reported in the East Indies In elevated tropic areas having colder climates more cases may be encountered and there is a parallel incidence of scarlatina erysipelas and puerperal fever Several clinicians have noted that the polyarthritic manifestations are relatively milder in the southern part of the United States compared with carditis and although classic inflammatory rheumatism is said to be rare in the Central and Great Plain States mitral stenosis is common Such data point to climatic influence on both incidence and clinical manifestations

Most cases occur in the late winter and early spring the season of most frequent respiratory infection

Damp areas such as water fronts and concealed water courses seem to favor development of the disease possibly because in these zones occurs more poverty with its attending malnutrition crowding and unhygienic environment conducive to the spread of respiratory infections Rheumatic fever is more prevalent among the poor than in the well to do Coburn found a ratio of 20 1 in New York City and Gunewardene observed

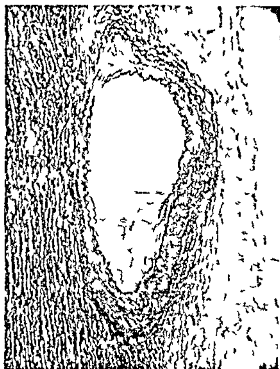

Fig 40 —Rheumatic lesion of coronary artery in a patient with accidental death nineteen days after onset of first attack of rheumatic fever Splitting of elastica and early embolus Weigert s elastica stain

a relatively high incidence among the poor in Ceylon

Multiple cases in a family are fairly common This may be due to at least two factors (1) an inherited tendency or weakness (2) common exposure to an infectious agent Not infrequently several members of a family show symptoms of upper respiratory streptococcal infection but only one develops rheumatic fever

The disease rare in infants begins to appear in children about five years of age increases in frequency until the age of nine to eleven after which the curve of relative in

cidence falls While most cases occur within the first three decades the infection is often active in later life, for example, Pappenheimer and von Glahn found 45 per cent of their active fatal rheumatic carditis in subjects more than thirty years old Polyarthritis is relatively more frequent among men Females, on the other hand suffer more from mitral stenosis in adults and from chorea among girls

Epidemics have been described in isolated communities boarding schools military camps hospital wards and convalescent homes These accompanied or followed epidemics of tonsillitis nasopharyngitis or scarlet fever which recent studies have shown to be due to Group A hemolytic streptococci This indicates that the contagious element resides in the precursory streptococcal disease

Bacteriology—There is very little conclusive evidence that non hemolytic streptococci occasionally recovered in blood cultures or at autopsy play a role in the causation of rheumatic fever Neither has any filtrable virus or pleuropneumonia like micro organism been shown to be etiologically important The agglutination of minute particles isolated from rheumatic exudates and once thought to be viral in origin (Schlesinger and co workers) was subsequently proven to be nonspecific (Eagles and Bradley) the particles are probably degeneration products of inflammatory cells or tissue

The most constantly demonstrable micro organisms associated with attacks of rheumatic fever are hemolytic streptococci belonging to Group A (Lancefield) These streptococci are demonstrable in the throats of between 50 and 75 per cent of patients at the time of onset of an attack of rheumatic fever On the other hand when it has been possible to make repeated cultures during the month prior to the onset Group A hemolytic streptococci have been demonstrated in almost all the patients Not infrequently they are present in nose cultures and absent in those from the throat and nasopharyngitis may be so mild as to escape detection without bacteriologic examination Obviously only a fraction of patients with streptococcal nasopharyngitis develop rheumatic fever, the proportion is much higher in those who have suffered previous rheumatic attacks Streptococci belonging to groups other than A do not induce attacks of rheumatic fever, neither does non streptococcal nasopharyngitis The prevention of both streptococcal respiratory infections and rheumatic fever by prophylactic doses of the sulfonamides is additional proof of the etiologic role of streptococci in respect to rheumatic fever

Most rheumatic fever patients develop relatively high titers of both antistreptolysin O and antifibrinolysins in their blood serum these are manifestations of the precursory hemolytic streptococcal infections Some observers (Coburn and others) claim that the antistreptolysin O titers are higher and more prolonged in rheumatic subjects than in nonrheumatics While this may be true when patients with simple streptococcal tonsillitis or nasopharyngitis are employed as controls those with more deep seated or persisting streptococcal infections have equally marked titers Todd Coburn and Hill have reported that rheumatic fever patients have a lower content of so called anti streptolysin S in their serum than do non rheumatic controls and that this anti streptolysin increases with recovery We have found that patients with prolonged low grade rheumatic fever were slower in developing type specific anti M precipitins than were streptococcus infected nonrheumatic subjects or rheumatic subjects who recovered rapidly The theory may thus be advanced that recovery from rheumatic fever is associated with the development of efficient type specific antistreptococcal immunity

How the hemolytic streptococcus induces rheumatic fever is not known The symptoms appear not with the initial bacterial infection but after an interval of one to four or five weeks usually in the third week This is the period when bacterial allergy *i e* hyperergy appears after an infection Similar hyperergy may be induced in animals by focal injections and it is heightened by repeated foci of streptococci Hypoergy is induced by intravenous injections of similar micro organisms and by the development of type specific immunity The type specific immune capacity of an antistreptococcal serum runs parallel to its anti M precipitin

content Theoretically, then the development of a suitable degree of type specific immunity should result in the elimination of a streptococcal infection, while on the other hand chronic focal infection and only a low grade immunity might result in a hypergic state which would account in part for some of the rheumatic symptoms Such an hypothesis is at least reasonable

essential lesion) is a soluble poison of some sort as yet unrecognized

Symptoms —While this disease is usually considered as one having pyrexia toxemia and migratory polyarthritis as its main features this description is one of convenience only and other essential features must be kept in mind if its nature is to be clearly comprehended The symptoms of rheumatic

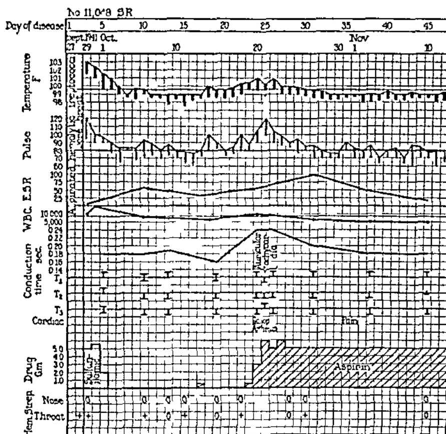

Fig 41 —Chart of a case of rheumatic fever induced by an accidental laboratory pharyngeal infection with hemolytic streptococci Although this streptococcal infection was controlled by sulfanilamide there were definite signs of rheumatic fever twenty days later These responded to aspirin During the so-called latent period (phase 2) the electrocardiogram showed diphasic T wave in lead 1 and negative T waves in leads 2 and 3 indicating cardiac involvement with the onset of rheumatic fever the PR interval increased to 0.24 of a second and there was auricular tachycardia The electrocardiogram returned to normal about the 75th day

The irritant might be particulate (bacterial bodies) or a soluble substance either from the streptococci their metabolic products or from the infected tissues Green and Collis claim that hemolytic streptococci may be cultured from the rheumatic heart valves but this has not been substantiated in our laboratory when strict surgical technique was used at the autopsy It seems more probable that the agent responsible for inducing the focal injury of the collagen (the

fever moreover as seen today are usually markedly altered by antipyretic drugs which while affording comfort also carry with them the danger of blinding both the physician and the patient to manifestations of infection in some important organ

Prodromata —Over half of the patients have tonsillitis or sore throat from one to four weeks prior to the rheumatic symptoms others a rhinitis which may be so mild as to escape notice Following this initial strepto

cidence falls While most cases occur within the first three decades the infection is often active in later life for example Pappenheimer and von Glahn found 45 per cent of their active fatal rheumatic carditis in subjects more than thirty years old Polyarthritis is relatively more frequent among men Females on the other hand, suffer more from mitral stenosis in adults and from chorea among girls

Epidemics have been described in isolated communities boarding schools, military camps hospital wards and convalescent homes These accompanied or followed epidemics of tonsillitis nasopharyngitis or scarlet fever which recent studies have shown to be due to Group A hemolytic streptococci *This indicates that the contagious element* resides in the precursory streptococcal disease

Bacteriology *—There is very little conclusive evidence that non hemolytic streptococci* occasionally recovered in blood cultures or at autopsy play a role in the causation of rheumatic fever Neither has any filtrable virus or pleuropneumonia like micro organism been shown to be etiologically important The agglutination of minute particles isolated from rheumatic exudates and once thought to be viral in origin (Schlesinger and co workers) was subsequently proven to be nonspecific (Eagles and Bradley) the particles are probably degeneration products of inflammatory cells or tissue

content Theoretically, then the develop ment of a suitable degree of type specific im munity should result in the elimination of a streptococcal infection, while on the other hand chronic focal infection and only a low grade immunity might result in a hyperergic state which would account in part for some of the rheumatic symptoms Such an hypoth esis is at least reasonable

essential lesion) is a soluble poison of some sort as yet unrecognized

Symptoms —While this disease is usually considered as one having pyrexia toxemia and migratory polyarthritis as its main fea tures this description is one of convenience only, and other essential features must be kept in mind if its nature is to be clearly comprehended The symptoms of rheumatic

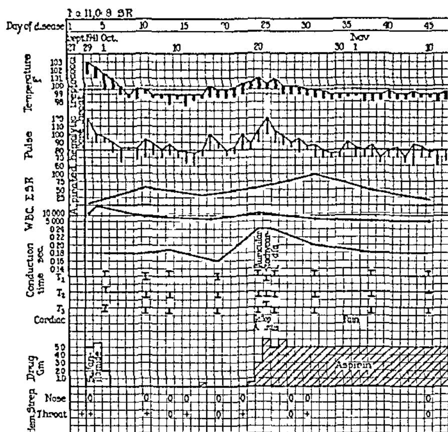

Fig 41 —Chart of a case of rheumatic fever induced by an accidental laboratory pharyngeal infection with hemolytic streptococci Although this streptococcal infection was controlled by sulfanilamide there were definite signs of rheumatic fever twenty days later These responded to aspirin During the so-called latent period (phase 2) the electrocardiogram showed diphasic T wave in lead 1 and negative T waves in leads 2 and 3 indicating cardiac involvement with the onset of rheumatic fever the PR interval increased to 0.24 of a second and there was auricular tachycardia The electrocardiogram returned to normal about the 75th day

The irritant might be particulate (bac terial bodies) or a soluble substance either from the streptococci their metabolic prod ucts or from the infected tissues Green and Collis claim that hemolytic streptococci may be cultured from the rheumatic heart valves but this has not been substantiated in our laboratory when strict surgical technique was used at the autopsy It seems more probable that the agent responsible for in ducing the focal injury of the collagen (the

fever moreover as seen today are usually markedly altered by antipyretic drugs which while affording comfort also carry with them the danger of blinding both the physician and the patient to manifestations of infection in some important organ

Prodromata —Over half of the patients have tonsillitis or sore throat from one to four weeks prior to the rheumatic symptoms others a rhinitis which may be so mild as to escape notice Following this initial strepto

coccal infection there is usually a latent period when the patient may feel perfectly well or have symptoms so slight that their significance is not evident until the onset of the rheumatism Careful study, both clinical and laboratory, of the patients in this latent phase not infrequently yields evidence of cardiac involvement

The onset of rheumatic symptoms may be gradual or acute apparently precipitated by chilling or overexertion Within a day the acute disease is often well developed, with a fever of 102° to 104° F, rapid pulse profuse perspiration, severe prostration, and polyarthritis It is rare for the inflammation to begin simultaneously in all of the joints, those most subject to stress and strain are first affected Initially monarticular arthritis is rare, it is more common to have the symmetrical joints simultaneously affected The striking feature of the arthritis is its migratory character, new joints are involved in rapid succession Various modes of extension described by different observers need not be here detailed While any joint in the body may be inflamed the large joints are most often implicated some claim that early involvement of the fingers and toes prognosticates a more chronic type of disease

A single involved joint usually manifests all the signs of acute inflammation *viz* pain tenderness swelling heat and local redness The swelling is due both to an effusion into the joint cavity and to edema of the periarticular structures Pressure from the exudate probably accounts to a considerable degree for the pain because there is often marked local relief following the aspiration of fluid from a joint Because of tenosynovitis the local manifestations must be considered not only as an arthritis but as an inflammation of any structure in proximity to a synovial membrane While the turbid fluid aspirated from these joints shows a marked increase in cells at times 20 000 to 30 000 per cubic millimeter suppuration does not occur unless there is secondary infection by pyogenic bacteria Disappearance of arthritis especially in children and young adults is accompanied by complete restoration of function without gross alteration in structure in older people on the other hand slight morning pain and stiffness often persist for several weeks

The polyarthritic form of the disease may be conveniently divided into monocyclic polycyclic and continuous In the first there is a single cycle of fever lasting from ten to fourteen days, the arthritis spreads from one set of joints to another with an increase in pyrexia as each new set is involved each joint is inflamed from four to six days then recovers and is not again affected after involvement of few or many of the joints the fever decreases the arthritis diminishes and the patient recovers without further manifestations In the polycyclic form on the other hand following a single cycle such as described there may be recurrence of another cycle of the same type or joints that have recovered may again become inflamed before completion of the first cycle and thus the two be superimposed The administration of salicyl shortens these cycles, but persistence of infection may be shown by the recurrence of arthritis and fever as the influence of the drug wears off In the continuous form the patient always presents some indication of active infection often varying in intensity from time to time In both the polycyclic and continuous forms the physician should be especially alert to detect serious involvement of the heart

Cardiac involvement is one of the most common features of rheumatic fever and is detected in proportion as our methods of examination are refined and applied Thus daily or semiweekly electrocardiograms showed transitory abnormalities in more than 95 per cent of our patients These variations occurring at any time may be the chief signs of a re awakening infection While such graphic records are impossible in all cases repeated careful physical examinations will frequently reveal evidence of cardiac involvement Obvious signs of cardiac embarrassment are easily detected and need not be here discussed but less marked signs require consideration Precordial pain and hyperesthesia point to myocardial involvement usually quite unaccompanied by pericarditis Gross changes in the size of the heart detectable by percussion are indicative of marked dilatation or of pericardial effusion Early significant roentgenographic alterations in the size of the heart are less frequent than would be expected

A diffuse precordial impulse wavelike in character indicates that the heart muscle is not contracting normally One can at times feel at the apex or just above and mesial to it, an extra impact synchronous with an intensified third heart sound This gives the palpatory evidence of a gallop more easily heard when felt however, it is a sign of unusual cardiac action

While it is impossible to be dogmatic concerning the interpretation of abnormal auscultatory signs much valuable information can be gained by listening to the heart daily Cardiac rate will be discussed later A change in auscultation rhythm is fairly common most frequently it is expressed as a gallop apparently due to an accentuation of the third heart sound which is at times as intense as the second sound Gallops usually come and go hand in hand with other evidence of cardiac involvement While most common in children and adolescents at an age when a third heart sound is most readily detectable they are often present in adults The tick tack rhythm of embryocardia is usually accompanied by obvious cardiac dilatation and other evidence of heart failure and is always a serious omen Aside from the usual sinus arrhythmia of children irregularities in rhythm are due to premature contractions to heart block usually partial or to auricular fibrillation Sometimes extrasystoles are frequent and regular enough to give coupled beats again they occur in uneven groups suggesting auricular fibrillation at other times they appear only once or twice a minute The regular dropping of a ventricular systole every four to seven beats points to partial heart block this suspicion can be confirmed by electrocardiograms Partial blocks usually persist only a few days Rarely complete heart block with bradycardia is encountered

Complete irregularity due to auricular fibrillation occasionally occurs and indicates a severe degree of cardiac involvement it usually is not persistent Some patients after recovering have resumed their normal laborious occupations without a return of cardiac irregularity

Murmurs detected during the course of an attack of rheumatic fever are difficult of interpretation especially when systolic in time Such systolic murmurs audible over the lower left precordium are frequent and usually explained as due to dilatation of the valve rings resulting in a slight relative insufficiency If we predicate that there is first an interstitial valvulitis with edema and subsequent deposition of verrucae we must conclude that some of the regurgitation at least is due to imperfect approximations of the leaflets Many patients have a very soft blowing diastolic murmur along the left sternal margin from the third to the fourth interspaces at times audible at the apex best heard by direct auscultation and unaccompanied by low diastolic pressure Occasionally such murmurs recur with other evidences of renewed infection Sometimes after recovery they disappear permanently again obvious signs of aortic insufficiency eventually develop The final significance of these murmurs must often be determined by studying the patient for months or years

While early interstitial inflammation doubtless at times prepares the valves for subsequent deformation more often crippling degrees of scarring depend upon long persistent or recurring involvement of the valves Not infrequently loud murmurs persist without cardiac embarrassment in patients who have fully overcome their infection, again only slight physical signs of valvular defects are found in others who are the subjects of marked cardiac insufficiency The degree of myocardial involvement therefore is as significant as the thickening of the valve or the dilatation of its ring

Pericarditis in rheumatic fever practically always is accompanied by an underlying myocarditis hence the importance of its detection Precordial pain occurring in a rheumatic fever patient is probably due more to a myocardium laboring under great handicap than to inflammation of the covering membranes One who awaits the appearance of precordial pain before suspecting pericarditis will fail to detect many instances for pericarditis often is unaccompanied by pain More significant is a to and fro friction rub which if of a double shuffle character is pathognomonic Such rubs may persist for days or occasionally last only a few hours With the accumulation of large amounts of fluid in the pericardial sac the rubs decrease or disappear they often persist however in spite of the outpouring of exudate The high

fibrin content of these exudates may explain in part the persistence of a rub and the insignificant reduction in the areas of precordial dulness and flatness after paracentesis Accumulation of exudate is indicated by increase in the area of precordial flatness and by a triangular area of marked dulness or flatness posteriorly in the region of the angle of the left scapula with distant bronchovesicular breath sounds and egophony over this area There occur also general symptoms and signs of weakened heart action dependent both upon pressure from accumulated fluid and upon concomitant myocarditis The patient should be followed upon recovery for signs of adhesions between the two layers of the pericardium for such adhesions are often the cause of severe permanent cardiac insufficiency

The *pulse* generally reflects the condition of the heart, hence alterations in cardiac rhythm and rate are immediately indicated in pulse records As alterations in rhythm have already been mentioned only rates or special features need be discussed here Early in polyarthritic forms of the disease acceleration in rate is proportional to the fever later it is indicative of myocardial damage Often a relapse in which the heart is the principal site of infection is indicated by rapid pulse If a high pulse rate persists in spite of normal temperature or low grade fever myocarditis should be suspected Marked and persistent increases in rate following slight exertion are very suggestive of injury to the heart muscle If on the other hand physical exertion induces a quickened pulse which soon returns to its original rate or slower it shows that the weakened heart action is probably hypotonic in origin and susceptible of improvement under regulated exercise A pulsus paradoxus sometimes accompanies severe pericarditis

Pleurisy occurring in 5 to 10 per cent of patients, is more frequent on the left side when it usually accompanies pericarditis It generally indicates a severe rheumatic infection but occasionally is the chief evidence of a relapse in a patient who has had polyarthritis weeks or months before Rarely it is the initial manifestation of rheumatic fever and probably certain cases of so called idiopathic pleurisy are rheumatic in origin

The onset of pleurisy is heralded by intensification of the signs of general infection and by characteristic sharp stabbing pain on inspiration With the accumulation of fluid the pain decreases but tachypnea at first the result of pain becomes more accentuated, due to the compression of lung and often to a concomitantly weakened myocardium Pleural exudate, as a rule need not be aspirated but at times, with marked embarrassment of respiration *paracentesis pleurae* adds much to the patient s comfort

While the occurrence of a true rheumatic pneumonia is controversial there is found in many subjects postmortem a pulmonic consolidation containing many large cells resembling those of rheumatic granulomata Often these lesions are near areas of vasculitis Pneumonic signs are difficult to interpret clinically for the accompanying pleural effusions and pericardial exudates or a dilated heart give a mixed picture At times the onset of pneumonia is reflected by renewed signs of infection again it is discovered only in careful routine physical examinations or in roentgenograms Blood streaked purulent sputum suggests pneumonia

Upper Respiratory—Hemolytic streptococcal infection of the nose paranasal sinuses pharynx pharyngeal lymphatic tissue and tonsils is probably the most frequent single feature of rheumatic fever While the sequence of nasopharyngitis latent period and rheumatic symptoms is common the latent period may be so shortened that the first and third phases are almost simultaneous In patients with subacute rheumatism recrudescence is often preceded or accompanied by signs of renewed paranasal sinusitis and relieved by disappearance of this condition Many rheumatic subjects especially children have chronically diseased tonsils enlarged satellite cervical lymph nodes and persisting redness along the anterior faucial pillars signs more indicative of chronically infected tonsils than is simple enlargement of these organs Accompanying acute attacks of polyarthritis there are sometimes diffuse pharyngeal redness and discomfort and both arthritis and pharyngitis respond to antirheumatic drugs indicating that they are comparable processes Laryngitis the result of spreading pharyngitis is not infrequent occasionally discrete nodules appear on the vocal cords very rarely acute

edema of the epiglottis and vocal cords is encountered a very serious complication

Respiration—In all patients there is an increased respiratory rate parallel with the fever and quickened pulse, but dispropor tionately rapid breathing may accompany pneumonia pleurisy or carditis Tachypnea as a concomitant of rheumatic carditis is especially noticeable in children in whom the rate may be from 50 to 70 per minute without any evidence of pulmonary infec tion Attacks of rapid breathing in adults may accompany extensive severe poly arthritis and merely reflect the extreme pain the patient is suffering in such instances the relief of pain by splinting or anodynes is fol lowed by a decreased respiratory rate

The *cutaneous manifestations* of rheu matic fever consist of various exudative dermatoses but none is absolutely typical of the disease as similar rashes are seen in other infections and apparently as inde pendent conditions Various types of erythema multiforme are the most common often the rash starts as flat papules rapidly increasing in size, and clearing in the centers finally the migratory borders of several lesions fuse into an extensive marginate erythema Frequently the evolution and resolution occur within a few hours Often such rashes recur for weeks or months They commonly do not itch hence may be easily over looked Occasionally purpura is seen Whether the syndromes included under Henoch s purpura and Schönlein s disease are of rheumatic origin it is impossible at present to decide

Erythema nodosum is an occasional com plication sometimes there is only a single outbreak in other patients there are re peated crops of painful subcutaneous indu rated areas with the overlying skin at first red later purple and greenish

Sudaminal eruptions following the severe sweating are usual manifestations of a severe febrile intoxication

Subcutaneous nodules one of the most im portant of the rheumatic series indicate that the patient s response to the infection is chiefly proliferative in nature and wide spread in distribution with concurrent myo carditis and valvulitis hence their existence is considered of serious if not of fatal prog nostic import but many patients with them recover and return to a normal useful life for years Being usually painless they must be diagnosed by inspection and palpation over the extensor aspects of joints along the spine and over superficial flat bony surfaces such as the skull scapula olecranon patella and malleoli they may also be seen in super ficially located tendons and tendon sheaths They are best demonstrated by placing the patient between the light and the examiner and having the skin over the suspected area tightly stretched usually by flexing the joint They then appear as white or light gray nodules from 1 to 10 mm in diameter connected with the deep fibrous tissue and not with the skin which is freely movable over them Palpation reveals them as hard and only slightly movable when the joints are flexed somewhat more so when extended If in the scalp or over the bellies of muscles they must be detected by palpation but as a rule let it be emphasized they are best found by inspection Conglomerate masses are often seen Each nodule persists for from a few days to several weeks and although of rapid evolution it usually undergoes more gradual resolution Often they occur in suc cessive crops so that in a given area nodules of various ages may be found They appear while the patient is saturated with sodium salicylate or aminopyrine and unlike rheu matic arthritis do not disappear quickly when the patient is placed fully under the influence of these drugs

Blood Picture—Not infrequently a washed-out waxy appearance is seen in pa tients who have undergone severe or pro longed attacks this is due to a secondary anemia the degree of which can be defi nitely determined by hemoglobin estimations and erythrocyte counts

Leukocyte counts made at weekly to fort nightly intervals furnish useful indices of the progress of the infection With high fever and polyarthritis there is a leukocytosis of 15 000 to 25 000 which decreases with the diminution of symptoms either spontaneous or drug induced In the monocyclic infection the count returns to and remains normal after a few weeks In polycyclic and continu ous forms on the other hand there is usu ally though not always a low grade leuko cytosis increasing prior to or with a clinical relapse Even with the patient under drugs

there may be a low grade leukocytosis to indicate persisting infection

Erythrocyte Sedimentation Rate—This in general is a good index of rheumatic activity The usual technic is that of Westergren and only in the presence of considerable anemia are corrections required for this factor In acute stages rates of 100 to 130 mm per hour are found With improvement the rate drops in monocyclic cases steadily to normal in chronic cases rates of 30 to 60 are long maintained Rates above 20 probably indicate continued rest In patients with chorea the rate is often normal Abnormal E S R curves are generally better indications of rheumatic infection than is leukocytosis Both considered together are better than either alone Other causes for abnormal rates should be eliminated in weighing their significance Recently Schultz has found the *formol gel* reaction to be abnormal in cases of apparently active rheumatic carditis where the E S R was normal

Nervous Manifestations—Delirium followed by coma may accompany hyperpyrexia rheumatica With moderate fever delirium occasionally occurs and sometimes there are other acute psychoses which may become fixed enough to require special institutional care Large doses of salicylates sometimes induce delirium

Bruetsch has described a remarkable frequency of rheumatic valvular deformities among insane patients in whom there were often areas of cerebral degeneration apparently secondary to rheumatic involvement of the cerebral blood vessels He suggests that this disease is responsible for approximately 4 per cent of insanity

Chorea is now considered one of the important rheumatic manifestations Accompanying most fatal chorea there is typical rheumatic carditis In the simple uncomplicated form however chorea may be considered one of the mildest of the rheumatic series When on the other hand chorea accompanies or follows polyarthritis or carditis the type of rheumatic infection should be regarded as unusually severe and liable to be followed by permanent cardiac damage In any case therefore the existence of chorea indicates that the child is 'rheumatic and hence should be protected from unusual stress and strain and specially guarded against hemolytic streptococcal infections

Kidneys—Albuminuria and cylindruria running roughly parallel with the pyrexia are fairly common Goldring and Wyckoff noted a marked increase in erythrocytes and casts as detected by Addis counts and persisting for eight or ten weeks Similar abnormalities of shorter duration appear about the third week after simple tonsillitis and there is more severe renal involvement of a similar nature after scarlet fever Occasionally rheumatic fever is accompanied by a true hemorrhagic nephritis from which recovery is usually complete Some clinicians claim that many cases of idiopathic nephritis are merely instances of isolated rheumatic kidney disease Large doses of salicylates sometimes induce hematuria and an outpouring of small castlike bodies neocinchophen induces similar signs of irritation aminopyrine rarely does All anti rheumatic drugs apparently lower the renal threshold for nonprotein nitrogen hence fever dehydration and drugs favor the formation of a urine containing an excess of urates

Gastro-intestinal Tract—Instead of upper respiratory prodromata attacks of rheumatism are sometimes preceded by mild gastroenteritis and very occasionally by signs of appendicitis Indeed symptoms of appendicitis in rheumatic subjects often warrant delaying operation until the effect of anti rheumatic drugs has been tested Gastric symptoms may result from the rheumatic intoxication antirheumatic drugs or cardiac failure In the first and third instances relief will follow proper medication in the second a change of drugs is often useful

Nutrition—In all types of rheumatic fever the general nutrition of the patient suffers In the acute forms the weight drops rapidly with recovery it is regained quickly In the subacute and chronic disease while the loss may be more gradual it is often correspondingly difficult to repair The weight curve is therefore an important guide to the patient s condition Continually falling or remaining subnormal it indicates that he is not overcoming the infection a sudden drop often heralds a relapse A steadily rising curve is favorable but persistent low grade infection is seen even in overweight patients Those taking large amounts of antirheuma

tic drugs often show a marked drop in weight due to severe sweating Occasionally when these drugs are given to the point of distinct renal irritation there is a sharp increase in weight due to edema In addition to the increased destruction of vitamins incident to most infections rheumatic fever patients usually show a decreased vitamin A content of the blood 50 to 80 per cent below normal (Shanks Coburn and Hoagland)

Rheumatic fever in children, unless acutely fatal usually runs a subacute or chronic course Frequently the infection is so insidious both in its onset and manifestations that the true nature of the illness in the young is unrecognized until the characteristic symptoms appear In this prerheumatic state or subclinical rheumatism the soil is probably prepared for later more serious damage hence suspicion of its existence indicates the closest study The various types of manifestations shown by children —polyarthritis pleurisy carditis chronic tonsillitis growing pains chorea and subcutaneous nodules—have been designated as the rheumatic series In general the combination of acute toxic and exudative manifestations so characteristic of the infection in adults is less marked in children on the other hand chronic low grade intoxication together with focal proliferative lesions furnish the usual picture in the young Arthritis is less extensive and more transitory there is usually carditis relapses are common Each relapse may be made manifest by only one or two members of the rheumatic series but over the course of years the entire gamut may be run A careful record of temperature sleeping pulse rate cardiac signs electrocardiograms and erythrocyte sedimentation rates has shown that children have o called subclinical rheumatic relapses with a frequency previously unsuspected With each relapse there are increasing signs of cardiac damage and unless the resisting capacity of the patient can be made sufficient to throw off the infection permanently the final picture is one of cardiac failure

If on the other hand the child contracts no more hemolytic streptococcal infections and hence suffers no rheumatic recurrences he may recover without permanent cardiac damage or with valves so slightly deformed that their normal function is little compromised Indeed murmurs considered as arising from diseased valves may disappear later in life

Diagnosis —Although Group A hemolytic streptococci apparently play such an important etiologic role immune reactions tested with streptococcal products have no definitive diagnostic import in respect to rheumatic fever but are indicative of the precursory streptococcal invasion In doubtful cases their absence is presumptive evidence against the existence of rheumatic fever The positive diagnosis of this disease therefore still rests mainly upon careful and well documented clinical observations

Following scarlet fever all the signs of true rheumatic fever may occur this is especially true if the patient has had a previous attack of rheumatism Puerperal sepsis may likewise precede rheumatic fever Common hemolytic streptococcal etiologic factors probably are at work in all

The migratory polyarthritis responding to certain drugs is a feature practically unduplicated by other diseases Early signs of cardiac involvement subcutaneous fibroid nodules persistent undernutrition low grade toxic state and concomitant chorea are all important aids in arriving at a correct diagnosis

Many infectious diseases are occasionally complicated by arthritis The antecedent history and positive evidence of the persistence of a specific infection are therefore important in determining the cause of a secondary arthritis In most purulent arthritides the causative micro organism is demonstrable in aspirated synovial fluid and immediate microscopic examination will at times settle the diagnosis At other times one must await the results of cultures Patients with gonorrheal rheumatism often have migratory serous polyarthritis but eventually one or two joints become persistently involved with a boggy edema and gonococci can usually be grown from the aspirated purulent synovial fluid if proper culture media are employed A history of gonorrhea the demonstration of gonococci in the genitourinary tract and of complement binding antibodies in the blood serum are important differential points Rapid disappearance of symptoms and signs of arthri

tis usually follow adequate doses of the *sulfonamides*

About half of the patients with undulant fever have arthritis involving principally the shoulders hips and knees Other features of the disease and demonstration of agglutinins and opsonins in the blood serum for Brucella confirm the diagnosis

In children acute septic arthritis and osteomyelitis may be mistaken for rheumatism Diagnosis is made by the extremely toxic state of the patient bogginess of the joint purulent character of the aspirated fluid and demonstration of staphylococci or streptococci in the synovial fluid and blood Hemophilia and scurvy in children also lead to painful swelling of the joints the nature of which should be determined from other features of these diseases

A subacute to chronic low grade polyarthritis with little if any demonstrable effusion is not infrequent following attacks of bacillary dysentery Whether sulfaguanidine will favorably affect this complication is as yet unknown

Rheumatoid arthritis or chronic secondary infectious arthritis sometimes begins acutely with features closely resembling rheumatic fever The initial and persistent involvement of small joints of the hands feet and spine and the comparative freedom from cardiac complications are suggestive features The persistence of periarticular swelling leading to obvious deformity confirms the diagnosis

Acute gout must sometimes be considered Family and personal history the deposits of tophi in the ears and of urates about the joints and the almost pathognomonic x ray picture of the bones should clear up any doubt A high uric acid content in the blood is very suggestive and a disappearance of the arthritis under adequate doses of colchicine is diagnostic

Polyarthritis is one of the most striking symptoms of serum disease following antitoxic or antibacterial serum therapy Marked pain and stiffness of the joints with very slight if any effusion absence of periarticular swelling and redness a coexistent urticaria and the history of serum treatment within a period of ten to twenty days serve to determine the nature of the trouble
